Dr. V Chandra Shekhar
Program Head
AIML
Faculty of Engineering and Technology,
Jain (Deemed to be University) Bengaluru

ACKNOWLEDGEMENT

We wish to express our deep gratitude to our guide **DR. ARCHANA SASI** for all advice, encouragement and constant support she has given us throughout our project work. This work would not have been possible without her support and valuable suggestions.

We sincerely thank to our respected Program Head **Dr. V CHANDRA SHEKHAR** for his great support in doing our project in **"PREDICTION OF LUNG CANCER USING MAXCHINE LEARNING ALGORITHM"** We would like to thank all our **friends** for their help and constructive criticism during our project work. Finally, we have no words to express our sincere gratitude to our **parents** who have shown us this world and for every support they have given us.

ABSTRACT

The recent development of imaging and sequencing technologies enables systematic advances in the clinical study of lung cancer. Machine learning based approaches play a critical role in integrating and analyzing these large and complex datasets, which have extensively characterized lung cancer through the use of different perspectives from these accrued data. The utilization of machine learning (ML) technique can significantly expedite the process of cancer detection and stage classification, enabling researchers to study a larger number of patients in a shorter time frame and at a reduced cost applying the image segmentation approach herein, the multiresolution rigid registration mechanism is applied to enhance the segmentation further.

Image processing methods such as noise reduction, feature extraction, identification of damaged regions, and maybe a comparison with data on the medical history of lung cancer are used to locate portions of the lung that have been impacted by cancer. This research shows an accurate classification and prediction of lung cancer using technology that is enabled by machine learning and image processing. To begin, photos need to be gathered. The geometric mean filter is used for the picture pre-processing. As a consequence, image quality is enhanced. The K-means technique is then used to segment the images. The part of the image may be found using this segmentation. Then, classification methods using machine learning will be used. For the classification, Artificial neural networks(ANN),k-nearest neighbours (KNN), and random forests(RF) are some of the machine learning techniques that will be used in our project. Our proposed models have the potential to be implemented in clinical settings to provide support to doctors in the early diagnosis of lung cancer, while minimizing the occurrence of false positives in scans.

1. INTRODUCTION

1.1 Introduction

Lung cancer is one of the most frequently diagnosed cancers and the leading cause of cancer deaths worldwide. About 2.20 million new patients are diagnosed with lung cancer each year and 75% of them die within five years of diagnosis . High intra-tumor heterogeneity (ITH) and complexity of cancer cells giving rise to drug resistance make cancer treatment more challenging Over the past decades, the continuous evolution of technologies in cancer research has contributed to many large collaborative cancer projects, which have generated numerous clinical, medical imaging, and sequencing databases These databases facilitate researchers in investigating comprehensive patterns of lung cancer from diagnosis, treatment, and responses to clinical outcomes In particular, current studies on -omics analysis, such as genomics, transcriptomics, proteomics, and metabolomics, have expanded our tools and capabilities for research. Cancer studies are undergoing a shift toward the integration of multiple data types and mega sizes. However, using diverse and highdimensional data types for clinical tasks requires significant time and expertise even with assistance from dimension reduction methods such as matrix and tensor factorizations and analyzing the exponentially growing cancer-associated databases poses a major challenge to researchers. Therefore, using machine learning (ML) models to automatically learn the internal characteristics of different data types to assist physicians' decision-making has become increasingly important.

Within this landscape of abundant data, machine learning algorithms emerge as powerful tools with the potential to revolutionize the way we approach the analysis of complex medical datasets. Among these algorithms, clustering techniques like k-means hold particular promise for unraveling intricate patterns within the data and facilitating predictive insights related to lung cancer. By leveraging the principles of unsupervised learning, k-means clustering excels at partitioning datasets into distinct clusters based on the similarities of their features. In the realm of lung cancer prediction, this capability opens doors to uncovering hidden relationships and subgroups among patients that may hold critical implications for prognosis and treatment strategies.

The application of k-means clustering in the realm of lung cancer prediction is multifaceted, offering a lens through which to explore the diverse facets of patient data and medical records. Through the lens of k-means, researchers and healthcare professionals can

delve into clusters of patients sharing common attributes such as demographic profiles, genetic markers, or imaging characteristics. This clustering process not only aids in revealing nuanced subtypes of lung cancer but also sheds light on the intricate interplay between various patient parameters and disease outcomes. By segmenting patient populations into meaningful clusters, k-means enables a more refined understanding of the complexities inherent in lung cancer and paves the way for personalized, data-driven healthcare solutions.

The implementation of k-means clustering in the context of lung cancer prediction entails a series of meticulous steps aimed at extracting actionable insights from the data. From the initial stages of data preprocessing and feature selection to the pivotal task of determining the optimal number of clusters, each phase of the process plays a crucial role in shaping the outcomes of the analysis. Once clusters are delineated, researchers can delve into the characteristics that define each group, identifying key features that differentiate high-risk from low-risk patients. Armed with this knowledge, predictive models can be developed, clinical decisions can be informed by data-driven insights, and treatment regimens can be tailored to the unique needs of individual patients.

In essence, the utilization of k-means clustering for lung cancer prediction marks a significant stride toward harnessing the potential of machine learning to revolutionize cancer care. By leveraging the capabilities of this algorithm, healthcare professionals are empowered to enhance early detection efforts, refine diagnostic accuracy, and ultimately, save lives through timely interventions and personalized treatment approaches. As the journey toward combating lung cancer continues, the fusion of data science and medical expertise promises to usher in a new era of precision medicine, where each patient's journey is guided by the insights gleaned from the intricate web of data that surrounds them.

1.2 Motivation

The correct identification and prediction of lung cancer using machine learning and image processing techniques have shown significant promise in improving early diagnosis and treatment outcomes. The process begins with the collection and pre-processing of images, typically CT scans, which are essential for capturing detailed lung structures. However, these images often contain noise and artifacts that can obscure important details. To address this, image filtering methods are employed, with the geometric mean filter being particularly effective in this context. This filter smooths the images while preserving crucial edge details, which is vital for subsequent processing steps.

Preprocessing of images is a critical step for the correct classification of disease images. Noise and artifacts are common problems in CT scans, and the geometric mean filter is used to reduce these issues. This preprocessing step ensures that the images are clean and informative, facilitating more accurate analysis. Additionally, to handle the high dimensionality of image data and reduce the computational load, linear discriminant analysis (LDA) is applied. LDA minimizes the feature subspace, ensuring that essential characteristics are retained without overfitting. This technique identifies the subspace that maximizes class separability, making it easier for machine learning models to distinguish between different categories of images.

Segmentation plays a vital role in any medical image processing technique as it separates useful components of an image from irrelevant ones. The K-means clustering method is often employed for this purpose. K-means partitions the image into non-overlapping clusters, with each cluster having its reference points to which pixels are assigned. This method effectively isolates regions of interest (ROIs), such as potential tumor areas, from surrounding tissues. By doing so, it facilitates a more focused analysis and improves the accuracy of subsequent classification steps.

Once the images are segmented, machine learning techniques are employed to categorize the identified regions. Artificial neural networks (ANNs) are particularly effective for this task. ANNs are computing systems inspired by the way the human brain works, consisting of a large number of interconnected artificial neurons or nodes. These nodes are linked by adjustable weights that enable the network to learn from predefined categorized images. During the training phase, the ANN is exposed to a vast dataset of labeled images, allowing it to learn the distinctive features associated with lung cancer. The network adjusts its weights through multiple iterations to minimize classification errors. Once trained, the ANN can process new, unseen images and accurately categorize them based on learned patterns.

The combination of geometric mean filtering, LDA, K-means clustering, and ANNs offers a powerful framework for lung cancer detection. The pre-processing steps ensure that the images are clean and informative, while LDA reduces dimensionality, making the dataset manageable for computational models. K-means clustering effectively segments the images, isolating areas of interest for detailed analysis. Finally, the ANN leverages its learned knowledge to make precise classifications. However, there are challenges associated with this approach. The quality of the initial image data is paramount; poor-quality images can lead to inaccurate preprocessing and segmentation, ultimately affecting the classification results.

Furthermore, the ANN's performance is highly dependent on the quality and diversity of the training data. A comprehensive and well-labelled dataset is essential to ensure that the network generalizes well to new images.

1.3 Project Idea

The major idea of our project is to develop a model for lung cancer detection using the K-means algorithm that can be a fascinating and have impactful endeavour. Here's an outline of a project idea for lung cancer detection utilizing the K-means algorithm:

Project Description:

- **Dataset Collection:** Gather a dataset comprising various features related to lung cancer, such as patient demographics, medical history, imaging data (e.g., CT scans), and diagnostic outcomes.
- **Data Pre-processing:** Clean and preprocess the dataset by handling missing values, normalizing features, and converting categorical data into numerical format.
- **Feature Selection:** Identify relevant features that are crucial for lung cancer detection, such as nodule size, shape, texture, and location within the lungs.
- **K-means Clustering:** Implement the K-means algorithm to cluster the lung cancer data based on similar characteristics or patterns. This clustering can help identify distinct groups of patients or lung nodules with similar attributes.
- **Model Training:** Split the dataset into training and testing sets, then train the K-means algorithm on the training data to learn patterns and clusters within the lung cancer features.
- **Evaluation:** Evaluate the performance of the K-means model by assessing its ability to accurately cluster lung cancer data and detect patterns that may indicate the presence of cancerous nodules.
- **Visualization:** Visualize the clustering results to gain insights into the different groups of patients or nodules identified by the K-means algorithm.
- **Prediction:** Use the trained K-means model to predict and classify new instances of lung cancer data into appropriate clusters, aiding in the early detection and diagnosis of lung cancer.

By embarking on this project, we can contribute to the advancement of lung cancer detection methodologies using machine learning techniques, potentially leading to improved diagnostic accuracy and patient outcomes in the field of oncology.

1.4 Scope

Predicting lung cancer through machine learning (ML) is a multifaceted endeavour that encompasses several critical stages. Initially, data collection involves gathering diverse datasets, including medical imaging data like CT scans and X-rays, clinical information such as patient demographics and medical history, and genetic data if available. Pre-processing these datasets is essential to ensure their quality and consistency, involving tasks like image normalization, feature extraction, and handling missing data. Feature engineering plays a pivotal role in extracting meaningful information from raw data, encompassing radiomic features from medical images, clinical features from patient records, and genomic features from genetic data. The integration of these diverse feature sets enhances the predictive power of the model. Model development involves selecting appropriate ML algorithms, including supervised learning models like logistic regression, support vector machines. Training and validation of the models are crucial, utilizing techniques like cross-validation and hyper parameter tuning to optimize performance and ensure robustness. Evaluation metrics such as accuracy, precision, recall, and F1-score are employed to assess the model's predictive ability. By leveraging the capabilities of ML, researchers and healthcare professionals can make significant strides in early detection, diagnosis, and treatment planning for lung cancer, ultimately improving patient outcomes and reducing mortality rates.

Predicting lung cancer using ML is not without challenges. One significant hurdle is the availability and quality of data. Medical imaging data, though rich in information, can be voluminous and require specialized expertise for annotation and pre-processing. Clinical data may be scattered across different healthcare systems and stored in varying formats, making data integration and standardization challenging. Moreover, the imbalanced nature of medical datasets, where positive cases (lung cancer instances) are often outnumbered by negative cases, poses challenges for model training and evaluation. Feature selection and engineering also require domain expertise to identify relevant predictors while avoiding overfitting. Another challenge lies in the interpretability of ML models. Interpreting the underlying decision-making process of these models and understanding which features contribute most to

predictions is crucial for gaining trust from healthcare professionals and facilitating clinical decision-making.

Despite these challenges, the potential benefits of ML in lung cancer prediction are immense. ML algorithms have the capacity to analyze vast amounts of data, detect subtle patterns, and make predictions with high accuracy. Early detection of lung cancer can significantly improve patient outcomes by enabling timely intervention and treatment. Moreover, ML-based predictive models can assist clinicians in risk stratification, treatment planning, and personalized medicine, ultimately leading to more effective healthcare delivery and improved patient care. Continued research and collaboration between data scientists, clinicians, and healthcare stakeholders are essential for overcoming challenges and harnessing the full potential of ML in lung cancer prediction and management.

2. RELATED WORK

The authors [1] experimented to assess the impact of the referral course and side effects on delays in a fast outpatient indicative programme for suspected lung cancer patients, as well as to determine whether delays were associated with sickness stage and outcome. There has been a thorough examination of the characteristics of tumours, their organisation, and the many deferrals that have occurred. A total of 565 patient restoration schematics were collected for this study. In total, 51% of the participants had lung growths while the other half (8.5%) had a variety of injuries, with 111 people (19.6%) having radiological anomalies that were not regarded to be potentially life-threatening. When it came to hemoptysis, first-line wait times were much lower than in other cases. In conclusion, it is recommended that support vector machines be used as a characterization technique.

At the beginning of their research, the authors [2] devised a technique to detect lung growth. Data reprocessing is carried out in this manner to kick off the process of enhancing the photograph. When the datasets are ready for testing under information mining and neural systems, which are both crucial to distinguishing across rehabilitative methods, this is the point at which they can be tested. Using back-propagation neural networks to classify information images as either malignant or noncancerous, the researchers were able to accomplish the desired result (BPNN). People who work in medicine figure out which stage of malignancy will be most helpful to them when they make a diagnosis. This work [3] employed network-based biomarker identification and quality set improvement strategies to find and approve characteristics linked with lung cancer progression and related pathways. They found that, in addition to the traits predicted by prior findings in these areas, the data revealed a wide range of innovative and surprising qualities with putative physiological capacities in smoking, which were not predicted by earlier findings in these areas.

A network-based technique was devised by [4] to deal with observable confirmation of smoking and classifying between the qualities associated with lung tumour survival and those associated with non-smoking groups and identifying all of the qualities associated with lung tumour survival and those associated with non-smoking groups. It has been shown that a six-quality mark connected with smoking can predict the risk of lung expansion and the likelihood of survival. People who smoke may be able to see and identify lung growth if this quality mark is used. They [5] employed information mining and streamlining approaches to generate findings from a large number of datasets to investigate lung growth. It can be used to find and

exploit malignancy patterns in databases. These patterns, which are found in databases, can then be used to predict the outcome of an illness based on the specific therapeutic instances that have been stored in the databases.

There is no denying that the authors [6] have been working on the application of various artificial intelligence techniques for detecting diseases and providing medications for quite some time now [6]. An artificial neural network (ANN) can be used to analyse data about breast cancer. The data from microarrays and the UCI machine learning library can be used to detect the emergence of lung cancer using multilayer feedforward neural networks that are similar to ANNs. Here, we provide a brief overview of the most recent relevant works for the prediction of lung cancer occurrence using ML techniques and models. Firstly, in [7], the authors demonstrated an efficient approach for the detection and classification of lung cancer by exploiting CT scan images. They employed seven classification models, such as a decision tree, random forest, support vector machine, naive Bayes, k-nearest neighbors, stochastic gradient descent and multi-layer perceptron. For the training and testing of these classifiers, a dataset of 15,750 clinical data, containing 6910 benign and 8840 malignant lung cancer-related images, was considered. In the acquired outcomes, the multi-layer perceptron classifier achieved superior accuracy, with a value of 88.55% in relation to the other classifiers. Similarly, in [8], the authors applied a neural network, radial basis function network, support vector machine, logistic regression, random forest, J48, naive Bayes and K-nearest neighbours in order to predict lung cancer. They showed that the radial basis function network achieved a higher accuracy of 81.25% on lung cancer data. Additionally, the key objective of [9] is the early diagnosis of lung cancer by examining the performance of classification algorithms. The authors applied classification algorithms, such as naive Bayes, support vector machine, decision tree and logistic regression. In the lung cancer dataset from the UCI, the logistic regression achieved higher accuracy of 96.9%, while in the lung cancer dataset from the data.world, support vector machine achieved a higher accuracy of 99.2%.

Cancer diagnosis using machine learning algorithms Maleki et al. [10] used the k-Nearest Neighbor (kNN) algorithm on the lung cancer dataset. They applied feature selection on the dataset and came up with the six most essential features among the dataset features. This paper uses the same feature selection algorithms in our proposed framework to develop the important features [10, 11]. While an increasing body of work applied SVM and decision tree algorithms to diagnose different types of cancer [12, 13–16]; there is little work used Gradient Boosting algorithm for this purpose. To this end, we use two traditional algorithms (SVM and Decision Tree) in literature along with GB in our framework. The healthcare system is quite

different from other industries, so it has a higher priority and customers in this area. In other words, regardless of its costs, patients expect the highest level of treatment and service. Since machine and deep learning have been successful in different areas and have provided precise solutions, they are considered fundamental methods for solving health problems [17].

3. PROBLEM STATEMENT/OBJECTIVES

Despite advancements in medical technology, the survival rate for lung cancer remains low, primarily because it is often diagnosed at advanced stages when treatment options are limited and less effective. Early detection significantly improves prognosis and survival rates, yet current screening methods, such as low-dose computed tomography (LDCT), are not universally accessible and carry the risk of false positives and radiation exposure.

The primary objective of our project is to develop a robust, accurate, and interpretable machine learning model for the early prediction of lung cancer. By integrating diverse data types and leveraging advanced ML algorithms, this model aims to identify high-risk individuals early, facilitating timely intervention and improving patient outcomes. The ultimate goal is to provide a tool that can be seamlessly integrated into clinical workflows, aiding in the reduction of lung cancer mortality through earlier and more accurate detection.

The challenge lies in developing a non-invasive, cost-effective, and accurate predictive model for lung cancer that can be used as a preliminary screening tool. Machine learning (ML) algorithms offer a promising solution by leveraging large datasets to identify patterns and risk factors associated with lung cancer. However, creating an effective ML model involves several critical challenges:

4. CONCLUSION

The utilization of machine learning (ML) models for early detection and prediction of lung cancer presents a transformative approach in medical diagnostics, with the potential to significantly improve patient outcomes and reduce mortality rates. The integration of diverse ML algorithms, such as naïve Bayes, logistic regression, support vector machines (SVM), decision trees, random forests, and artificial neural networks, has demonstrated promising results in achieving high accuracy in lung cancer detection. Each algorithm brings unique strengths to the table, ranging from the simplicity and efficiency of naïve Bayes to the powerful classification capabilities of SVMs and the complex pattern recognition of artificial neural networks.

In the context of lung cancer detection, leveraging these ML techniques involves a comprehensive process. This includes the collection and integration of extensive datasets comprising demographic information, clinical records, genetic data, and imaging data. Pre-processing these datasets is crucial to ensure quality and consistency, while feature engineering and selection play vital roles in deriving meaningful insights from the raw data. The K-means clustering algorithm is particularly highlighted in our project for its ability to group patients based on risk factors, facilitating the identification of high-risk individuals. By employing advanced image processing techniques and explainable AI tools, our project aims to enhance the interpretability and accessibility of the results for healthcare professionals. This is essential for clinical decision-making and ensuring that the model's predictions are both reliable and actionable.

The development of a non-invasive, cost-effective, and accurate predictive tool addresses the limitations of current screening methods, such as low-dose computed tomography (LDCT), which can be invasive, expensive, and carry risks of false positives and radiation exposure. The proposed system aims to be user-friendly, scalable, and integrated into clinical workflows, providing real-time risk assessments and visualizations to support early intervention. Clinical validation is a critical phase of the project, involving real-world testing and feedback from healthcare providers. This ensures the model's robustness, reliability, and effectiveness in actual clinical settings. Performance metrics such as cluster purity, precision, recall, and overall accuracy will guide continuous improvement and refinement of the model.

In summary, this project seeks to revolutionize lung cancer screening and diagnosis through the innovative application of machine learning. By identifying high-risk individuals at an early stage, the system can enable timely medical intervention, significantly improving patient outcomes and reducing lung cancer mortality. The project also contributes to the broader field of AI in healthcare, demonstrating the potential of machine learning algorithms to address complex medical challenges and guiding future research and public health strategies for lung cancer prevention and management.

Faculty of Engineering & Technology JAIN (Deemed to-be University)

ACKNOWLEDGEMENT

It is a great pleasure for me to acknowledge the assistance and support of a large number of individuals who have been responsible for the successful completion of this project work.

First, I take this opportunity to express my sincere gratitude to the Faculty of Engineering & Technology, JAIN (Deemed to-be University) for providing me with a great opportunity to pursue my Bachelor's Degree in this institution.

I am deeply thankful to several individuals whose invaluable contributions have made this project a reality. I wish to extend my heartfelt gratitude to **Dr. Chandraj Roy Chand, Chancellor**, for his tireless commitment to fostering excellence in teaching and research at Jain (Deemed-to-be-University). I am also profoundly grateful to the honorable **Vice Chancellor, Dr. Raj Singh, and Dr. Dinesh Nilkant, Pro Vice Chancellor**, for their unwavering support. Furthermore, I would like to express my sincere thanks to **Dr. Jitendra Kumar Mishra, Registrar**, whose guidance has imparted invaluable qualities and skills that will serve us well in our future endeavors.

It is a matter of immense pleasure to express my sincere thanks to **Dr. V Chandrashekhar, Program Head of Computer Science and Engineering (Artificial Intelligence and Machine Learning)**, School of Computer Science & Engineering Faculty of Engineering & Technology for providing the right academic guidance that made my task possible .

I would like to thank our Project Coordinator & Mentor **Dr. Archana Sasi**, and all the staff members of Computer Science and Engineering for their support.

I am also grateful to my family and friends who provided me with every requirement throughout the course.

I would like to thank one and all who directly or indirectly helped me in completing the work successfully.

Abstract

Lung Cancer is one of the leading causes of cancer-related deaths worldwide. Early detection plays a crucial role in improving survival rates and enabling timely medical treatment. However, traditional diagnostic methods rely heavily on manual analysis of medical images such as CT scans, which can be time-consuming and prone to human error. With the rapid advancement of Artificial Intelligence and Deep Learning, automated systems have emerged as powerful tools for medical image analysis and disease detection.

This project presents a deep learning–based framework for the detection and classification of lung cancer using CT scan images. The proposed system utilizes Convolutional Neural Networks (CNNs) along with transfer learning techniques to automatically extract features from lung images and classify lung nodules as benign or malignant. Pre-trained deep learning architectures such as VGG16, ResNet50, and DenseNet121 are employed to improve classification accuracy and reduce training time.

The system includes several stages such as data acquisition, image preprocessing, data augmentation, model training, and performance evaluation. Image preprocessing techniques such as resizing and normalization are applied to standardize the input images, while data augmentation methods such as rotation and flipping are used to increase dataset diversity and prevent overfitting. These techniques help improve the robustness and generalization ability of the deep learning models.

Experimental results demonstrate that the proposed system achieves high performance in lung cancer detection, with strong evaluation metrics including accuracy, precision, recall, and F1-score. The trained model is capable of accurately identifying cancerous and non-cancerous lung nodules from CT scan images. Additionally, the system provides prediction results with confidence percentages, making it easier for users to interpret the classification outcome.

A simple user interface is also developed to allow users to upload CT scan images and obtain prediction results easily. This makes the system accessible and practical for real-world applications. The proposed framework can serve as a supportive diagnostic tool for healthcare professionals, helping radiologists detect lung cancer at an early stage and reduce diagnostic workload.

Overall, this project demonstrates the potential of deep learning in medical imaging and highlights how AI-driven systems can assist in improving the accuracy and efficiency of lung cancer diagnosis. The proposed model provides a reliable and scalable solution for automated lung cancer detection, contributing to the advancement of intelligent healthcare systems.

1.INTRODUCTION

Introduction

Lung cancer is one of the most serious and life-threatening diseases worldwide, accounting for a significant number of cancer-related deaths every year. The primary challenge associated with lung cancer is its late diagnosis, as symptoms often appear only in advanced stages. Early detection plays a crucial role in improving survival rates and enabling effective treatment. However, traditional diagnostic methods such as manual analysis of Computed Tomography (CT) scans are time-consuming, subjective, and prone to human error.

With the rapid advancement of Artificial Intelligence (AI) and Machine Learning (ML), automated systems have emerged as powerful tools for medical image analysis. In particular, Deep Learning (DL), a subset of ML, has demonstrated remarkable performance in processing large-scale image datasets and extracting meaningful patterns. Convolutional Neural Networks (CNNs) are especially effective in image classification tasks due to their ability to automatically learn spatial features from raw image data.

In the context of lung cancer detection, CNN-based models can analyze CT scan images to identify abnormal patterns, such as lung nodules, which may indicate the presence of cancer. These models eliminate the need for manual feature extraction and significantly improve diagnostic accuracy. However, training deep learning models from scratch requires large datasets and high computational resources, which may not always be feasible.

To address this limitation, Transfer Learning (TL) has been widely adopted. Transfer learning leverages pre-trained models such as VGG16, ResNet50, and InceptionV3, which have already been trained on large datasets like ImageNet. By fine-tuning these models on medical datasets, it becomes possible to achieve high accuracy even with limited data. This approach reduces training time and enhances performance.

In this project, a deep learning framework is proposed for early lung cancer detection and characterization using CNNs and transfer learning techniques. The system focuses not only on detecting the presence of cancer but also on characterizing lung nodules based on features such as size, shape, and texture. This helps in distinguishing between benign and malignant cases more effectively.

The proposed system includes several stages such as data collection, preprocessing, feature extraction, model training, and evaluation. Advanced techniques like data augmentation and normalization are applied to improve model generalization. The trained model is then evaluated using standard performance metrics such as accuracy, precision, recall, F1-score, and AUC-ROC.

By integrating deep learning techniques into medical diagnostics, the proposed system aims to assist healthcare professionals in making faster and more accurate decisions. This can significantly reduce diagnostic errors and improve patient outcomes. The overall goal is to develop a reliable and efficient system that can support early

detection and characterization of lung cancer in real-world clinical scenarios.

Motivation

Lung cancer continues to be one of the leading causes of mortality across the globe, primarily due to delayed diagnosis and lack of efficient detection methods. Early-stage lung cancer often goes unnoticed because the symptoms are minimal or resemble other common respiratory conditions. As a result, many patients are diagnosed only in advanced stages, where treatment options are limited and survival rates are significantly reduced.

The increasing availability of medical imaging technologies such as CT scans has made it possible to detect lung abnormalities at earlier stages. However, analyzing these images manually is a complex and time-consuming process that requires expert radiologists. Human interpretation is also subject to variability and may lead to misdiagnosis in certain cases.

The motivation behind this project is to develop an automated and reliable system that can assist in the early detection and characterization of lung cancer using advanced deep learning techniques. By leveraging CNNs and transfer learning, the system can efficiently analyze medical images and identify patterns that may not be easily visible to the human eye.

Another key motivation is to reduce the workload of medical professionals and provide a supportive tool for decision-making. Automated systems can process large volumes of data quickly and consistently, thereby improving efficiency in healthcare systems. Additionally, early detection of lung cancer can significantly increase the chances of successful treatment and reduce mortality rates.

The project also aims to explore the potential of deep learning models in handling real-world medical datasets, addressing challenges such as limited data availability, class imbalance, and variability in imaging conditions. By overcoming these challenges, the system can be made more robust and applicable in practical scenarios.

Project Idea

The primary idea of this project is to design and develop a deep learning-based framework that can automatically detect and characterize lung cancer from CT scan images. The system leverages convolutional neural networks for feature extraction and classification, combined with transfer learning to enhance performance and efficiency.

The proposed framework begins with data collection, where a dataset of lung CT scan images is obtained. These images include both normal and cancerous cases. The dataset is then preprocessed to remove noise, normalize pixel values, and ensure consistency in image dimensions.

Next, a pre-trained deep learning model such as VGG16 or ResNet50 is used as the base architecture. The model

is fine-tuned to adapt to the lung cancer detection task. Feature extraction is performed automatically by the convolutional layers, which learn important visual patterns such as edges, textures, and shapes.

The system then classifies the images into different categories, such as benign or malignant. In addition to classification, the model also helps in characterizing the detected nodules based on their properties. This provides more detailed information that can assist in medical diagnosis.

Finally, the performance of the model is evaluated using various metrics, and the results are analyzed to assess its effectiveness. The system can be further enhanced by integrating visualization techniques to highlight the regions of interest in the images.

Scope

The scope of this project is focused on developing an efficient and accurate system for early lung cancer detection and characterization using deep learning techniques. The system is designed to work with medical imaging data, particularly CT scan images, to identify and classify lung nodules.

1. The project aims to implement CNN-based models for automated feature extraction and classification of lung images.
2. It utilizes transfer learning techniques to improve performance and reduce the need for large datasets and computational resources.
3. The system focuses on binary classification of lung nodules into benign and malignant categories, along with basic characterization features.
4. Performance evaluation is carried out using standard metrics such as accuracy, precision, recall, and F1-score.
5. The project also explores the challenges associated with medical image analysis, including data imbalance, noise, and variability.
6. The system is intended to serve as a supportive tool for healthcare professionals, not as a replacement for clinical diagnosis.

Overall, the project contributes to the field of medical image analysis by demonstrating the effectiveness of deep learning techniques in early disease detection and characterization.

Literature Survey

Early detection of Lung Cancer is crucial because it significantly improves treatment outcomes and patient survival rates. Over the past decade, many researchers have explored the use of Artificial Intelligence and Deep Learning techniques for automated lung cancer detection using medical images such as CT scans and X-rays. The literature survey reviews previous research work related to lung cancer detection and highlights the methods, datasets, and outcomes achieved by different researchers.

Study 1: Deep Learning for Lung Nodule Detection

Researchers have widely applied Deep Learning methods to analyze medical imaging data for cancer detection. One of the most commonly used approaches is the Convolutional Neural Network (CNN), which automatically extracts features from images without the need for manual feature engineering.

In several studies, CNN-based models were trained on CT scan images to detect lung nodules. The results showed that deep learning models could identify suspicious nodules with high accuracy compared to traditional image processing methods. These models significantly improved the detection rate and reduced the chances of human diagnostic errors.

Study 2: Transfer Learning in Medical Imaging

Many researchers have applied transfer learning to improve lung cancer detection systems. Transfer learning involves using pre-trained neural networks that were originally trained on large image datasets.

Popular architectures used in these studies include:

- VGG16
- ResNet50

These models have demonstrated excellent performance in medical image classification tasks. By fine-tuning the pre-trained networks with medical datasets, researchers achieved high accuracy while reducing training time and computational requirements.

Studies reported that transfer learning improves model performance even when the available medical dataset is relatively small.

Study 3: Lung Cancer Classification Using CNN Models

Several research works have focused on classifying lung nodules as benign or malignant using deep learning models. CNN architectures were used to automatically extract relevant features such as shape, texture, and intensity patterns from CT scan images.

The results from these studies indicated that deep learning-based models outperform traditional machine learning techniques such as:

- Support Vector Machines (SVM)
- Random Forest
- K-Nearest Neighbor (KNN)

CNN models achieved higher classification accuracy and better generalization ability.

Study 4: Dense Neural Networks for Medical Image Analysis

Another important model used in lung cancer detection research is DenseNet121. This architecture connects each layer directly to every other layer in a feed-forward fashion, allowing better feature propagation and reuse.

Studies using DenseNet-based architectures reported improved performance in detecting small lung nodules and subtle abnormalities in CT scan images. The dense connections help reduce the vanishing gradient problem and improve training efficiency.

Study 5: Data Augmentation for Improved Model Performance

Researchers have also emphasized the importance of data augmentation techniques in medical image classification. Since medical datasets are often limited, augmentation methods such as image rotation, flipping, zooming, and scaling are used to increase the diversity of training samples.

These techniques help deep learning models learn more generalized features and prevent overfitting. As a result, the model performs better when tested on new unseen images.

Summary of Literature Survey

From the reviewed literature, it is evident that deep learning techniques have become highly effective in medical image analysis and lung cancer detection. Most studies confirm that CNN-based architectures combined with transfer learning provide high accuracy and reliable performance.

Models such as VGG16, ResNet50, and DenseNet121 are widely used because they can extract complex features from medical images and classify lung nodules efficiently. Additionally, preprocessing and data augmentation techniques play a crucial role in improving model performance.

These research findings strongly support the development of an automated lung cancer detection system using deep learning methods. The proposed project builds upon these existing approaches and aims to develop a reliable and efficient system for early detection and classification of lung cancer.

2.RELATED WORK

With the rapid advancement of Artificial Intelligence and Deep Learning, medical image analysis has seen significant improvements, particularly in the field of cancer detection. Lung cancer detection using Computed Tomography (CT) images has been extensively studied, and various machine learning and deep learning techniques have been proposed to improve diagnostic accuracy and efficiency.

Early research in lung cancer detection primarily relied on traditional machine learning techniques such as Support Vector Machines (SVM), Decision Trees, and k-Nearest Neighbors (KNN). These methods required manual feature extraction, where domain experts had to identify relevant features such as texture, shape, and intensity from CT images. Although these approaches achieved moderate success, they were limited by their inability to capture complex patterns present in medical images.

With the emergence of deep learning, Convolutional Neural Networks (CNNs) became the preferred approach for medical image classification. CNNs automatically extract hierarchical features from raw images, eliminating the need for manual feature engineering. Researchers demonstrated that CNN-based models significantly outperform traditional methods in terms of accuracy and robustness.

In the work presented by various researchers, deep learning models such as AlexNet, GoogLeNet, and VGG16 have been successfully applied to lung cancer detection tasks. These models achieved high classification accuracy by learning complex spatial features from CT scan images. However, training deep networks from scratch requires large datasets and high computational power, which is often a limitation in medical applications.

To overcome these challenges, transfer learning has been widely adopted. Transfer learning utilizes pre-trained models that are trained on large datasets like ImageNet and adapts them to specific tasks such as lung cancer detection. Pre-trained architectures like VGG16, ResNet50, and InceptionV3 have shown remarkable performance improvements when fine-tuned on medical datasets.

In the published work on lung cancer detection using deep learning frameworks, a hybrid approach combining CNN and transfer learning techniques has been proposed. The model

utilizes VGG16 as a backbone architecture for feature extraction and integrates additional layers for classification. This approach significantly improves accuracy and reduces training time. The system also incorporates preprocessing techniques such as normalization, resizing, and data augmentation to enhance model generalization.

Furthermore, advanced architectures such as ResNet-50 have been explored due to their ability to overcome the vanishing gradient problem through residual learning. Residual connections allow the network to learn deeper representations without degradation in performance. Studies have shown that ResNet-based models achieve accuracy levels exceeding 98% in lung cancer classification tasks, demonstrating their effectiveness in handling complex medical image data.

DenseNet-121 is another architecture that has gained attention in recent research. DenseNet introduces dense connectivity between layers, enabling feature reuse and improving gradient flow. This architecture reduces the number of parameters while maintaining high performance. Experimental results indicate that DenseNet achieves high accuracy with better generalization compared to traditional CNN models.

In addition to CNN-based approaches, transformer-based models such as Vision Transformers (ViT) have been introduced for medical image analysis. Unlike CNNs, which focus on local features, ViT models capture global relationships within the image using self-attention mechanisms. Although ViT models show promising results, they often require large datasets and may not outperform CNNs in tasks that rely heavily on local spatial features, such as lung nodule detection.

Several studies have also focused on improving model performance through data augmentation techniques. Techniques such as rotation, flipping, scaling, and brightness adjustment are used to increase dataset diversity and reduce overfitting. Synthetic data generation methods such as SMOTE have also been employed to address class imbalance in medical datasets.

Another important aspect explored in recent research is model evaluation. Researchers use performance metrics such as accuracy, precision, recall, F1-score, and Area Under the Curve (AUC-ROC) to assess model effectiveness. These metrics provide a comprehensive understanding of model performance, especially in imbalanced datasets where accuracy alone may not be sufficient.

Despite significant advancements, several challenges remain in lung cancer detection using

deep learning. One of the major challenges is the limited availability of labeled medical datasets. Privacy concerns and data collection difficulties restrict the size of training datasets, which can affect model performance. Additionally, variability in imaging conditions, such as differences in CT scan quality and resolution, introduces complexity in model training.

Another challenge is the interpretability of deep learning models. Most deep learning models function as black-box systems, making it difficult for medical professionals to understand the reasoning behind predictions. This lack of transparency can limit the adoption of AI-based systems in clinical settings.

From the reviewed literature, it is evident that deep learning, particularly CNN and transfer learning-based approaches, have significantly improved lung cancer detection accuracy. Among various models, ResNet-50 demonstrates superior performance due to its deep architecture and residual learning capabilities. DenseNet and Vision Transformers also contribute valuable insights into alternative modeling approaches.

However, there is still a need for a robust framework that combines high accuracy, efficiency, and interpretability. The proposed system in this project aims to address these challenges by integrating transfer learning with advanced CNN architectures to achieve reliable lung cancer detection and characterization.

Overall, the literature indicates that deep learning-based methods are highly effective for medical image analysis and hold great potential for improving early diagnosis and treatment of lung cancer. Continued research in this field is expected to further enhance model performance and enable real-world clinical applications.

3.PROBLEM STATEMENT

Lung Cancer is one of the leading causes of cancer-related deaths worldwide. The major challenge in lung cancer treatment is that the disease is often diagnosed at an advanced stage, when treatment options are limited and survival rates are significantly lower. Early detection of lung cancer is therefore extremely important for improving patient outcomes and enabling timely medical intervention.

Traditional methods of diagnosing lung cancer primarily rely on the manual examination of CT scan or X-ray images by radiologists. Although medical imaging technologies have improved significantly, the process of analyzing these images is time-consuming and highly dependent on the expertise of healthcare professionals. In many cases, small lung nodules or subtle abnormalities may be difficult to detect, which can lead to delayed diagnosis or misclassification. Additionally, the increasing number of medical images generated in hospitals creates a heavy workload for radiologists, increasing the possibility of human error.

Another challenge in traditional diagnostic approaches is the difficulty in accurately distinguishing between benign and malignant lung nodules. Many nodules appear visually similar in CT scans, making it challenging for manual analysis to consistently provide reliable results. As a result, patients may undergo unnecessary invasive procedures such as biopsies or may experience delays in receiving appropriate treatment.

With the rapid advancement of Artificial Intelligence and Deep Learning, there is a growing interest in developing automated systems that can assist doctors in medical image analysis. Deep learning models, especially Convolutional Neural Networks (CNNs), have shown great potential in identifying complex patterns and features within medical images. These models can learn directly from data and automatically extract important features that may not be easily recognizable through traditional methods.

However, building an effective automated lung cancer detection system requires addressing several challenges. These include handling large volumes of medical imaging data, improving the accuracy of classification models, reducing computational complexity, and ensuring reliable

performance on unseen data. Additionally, medical datasets are often limited in size, which can affect the performance and generalization ability of deep learning models.

Therefore, there is a need to develop an efficient and reliable system that can automatically analyze CT scan images and accurately detect lung cancer at an early stage. The proposed solution aims to address this problem by utilizing advanced deep learning architectures such as VGG16 and ResNet50. These models use transfer learning techniques to extract meaningful features from lung CT scan images and classify lung nodules as benign or malignant.

The main goal of this project is to design and implement a deep learning-based system that improves the accuracy, efficiency, and reliability of lung cancer detection. By automating the analysis of CT scan images, the proposed system can support healthcare professionals in making faster and more accurate diagnoses. This can ultimately contribute to early detection of lung cancer, reduce diagnostic errors, and improve the overall quality of healthcare services.

Objectives

The main objective of this project is to develop an automated system for the early detection and classification of Lung Cancer using advanced deep learning techniques. The system aims to analyze CT scan images and assist healthcare professionals in identifying lung nodules as benign or malignant with high accuracy. By integrating Artificial Intelligence and Deep Learning, the project focuses on improving the efficiency and reliability of medical image analysis.

Primary Objective

The primary objective of this project is to design and implement a deep learning–based model that can automatically detect lung cancer from CT scan images and accurately classify lung nodules into benign or malignant categories.

Specific Objectives

1. To develop an automated lung cancer detection system

The project aims to build a system capable of analyzing lung CT scan images and identifying cancerous nodules using deep learning techniques.

2. To apply Convolutional Neural Network models for image classification

The system utilizes advanced CNN architectures such as VGG16, ResNet50, and DenseNet121 to extract meaningful features from medical images.

3. To implement transfer learning for improved performance

Transfer learning techniques are used to leverage pre-trained models, which help reduce training time and improve classification accuracy even with limited medical datasets.

4. To perform image preprocessing and data augmentation

Preprocessing techniques such as resizing, normalization, and noise reduction are applied to improve image quality, while data augmentation methods increase dataset diversity and reduce overfitting.

5. To evaluate model performance using standard metrics

The effectiveness of the system is measured using evaluation metrics such as accuracy, precision, recall, F1-score, and confusion matrix analysis.

6. To visualize prediction results with confidence percentages

The system provides prediction outputs along with probability scores to help users understand the model's confidence in its classification.

7. To develop a simple user interface for easy interaction

A user-friendly interface is created to allow users to upload CT scan images and receive instant predictions from the trained model.

Summary

The overall objective of this project is to create a reliable and efficient deep learning-based system that can assist in the early detection of lung cancer. By automating the analysis of CT scan images, the system aims to support healthcare professionals in making faster and more accurate diagnoses, ultimately improving patient care and treatment outcomes.

4.METHODOLOGY

The proposed system follows a structured pipeline that integrates deep learning techniques for accurate lung cancer detection and characterization. The methodology consists of several stages, including data collection, preprocessing, feature extraction, model training, and evaluation.

4.1 System Overview

The system is designed as an end-to-end deep learning pipeline that takes CT scan images as input and produces classification results indicating whether the detected lung nodules are benign or malignant.

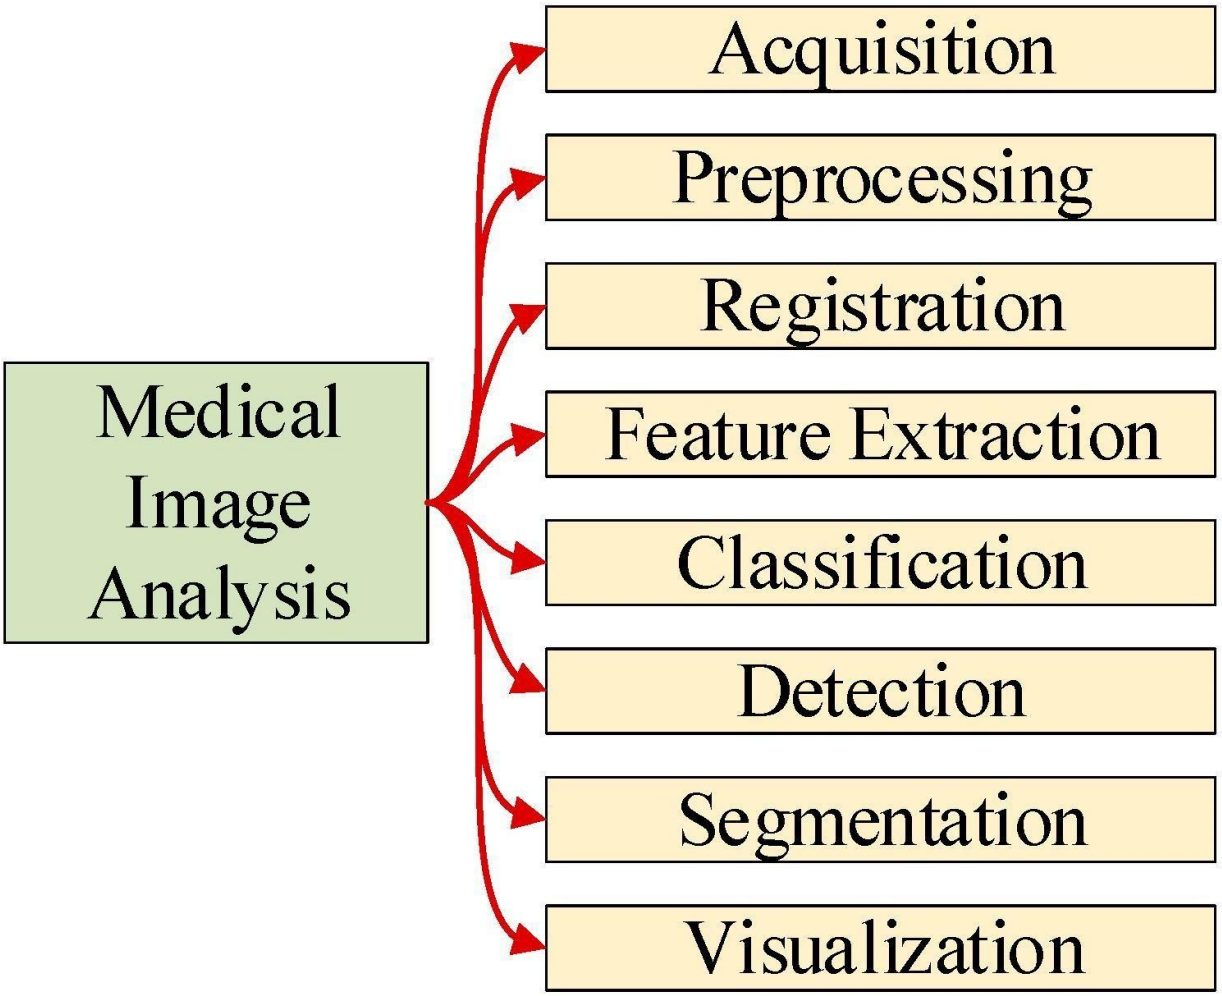
Final Prediction



The overall workflow of the system includes:

1. Input CT scan images
2. Image preprocessing and normalization
3. Feature extraction using CNN models
4. Classification using transfer learning models
5. Performance evaluation

4.2 Data Collection

The dataset used in this project consists of lung CT scan images obtained from publicly available medical imaging repositories. The dataset includes both normal and abnormal cases, with labeled information indicating the presence or absence of cancerous nodules.

The dataset is divided into:

- Training dataset
- Validation dataset
- Testing dataset

Proper dataset splitting ensures that the model is evaluated effectively and prevents overfitting.

4.3 Data Preprocessing

Data preprocessing is a crucial step in improving the performance of deep learning models. Medical images often contain noise, inconsistencies, and variations in size and resolution.

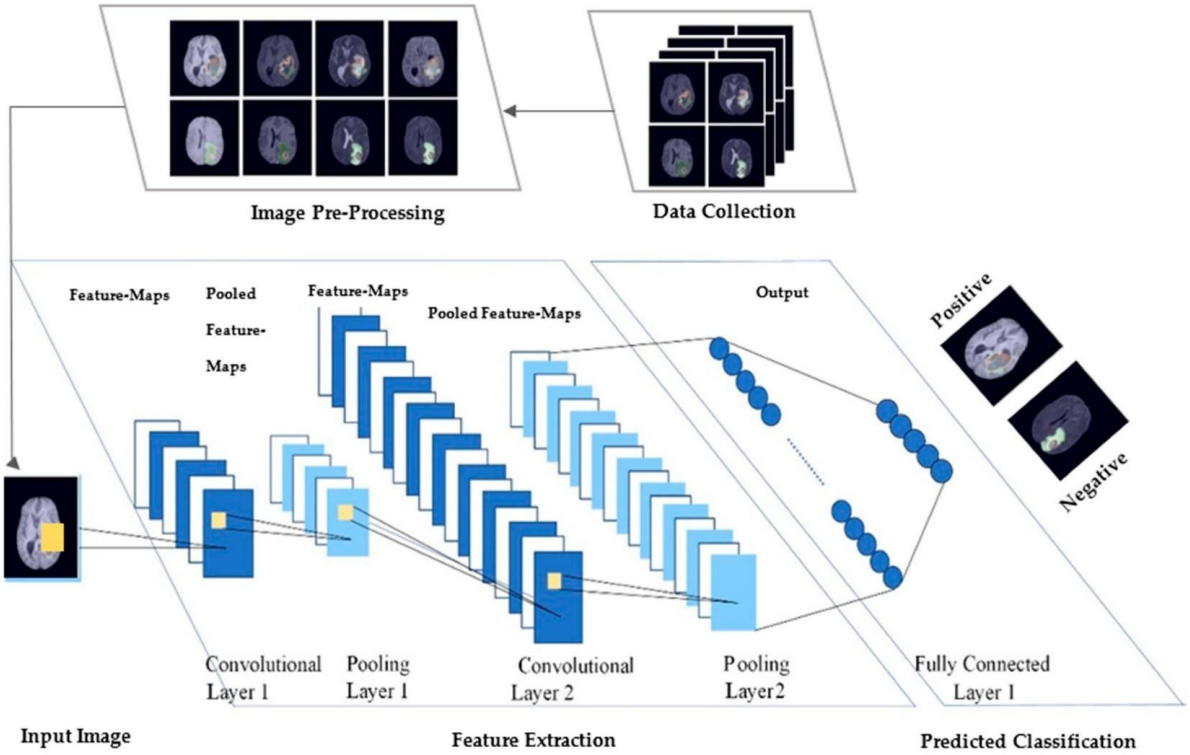
The preprocessing steps include:

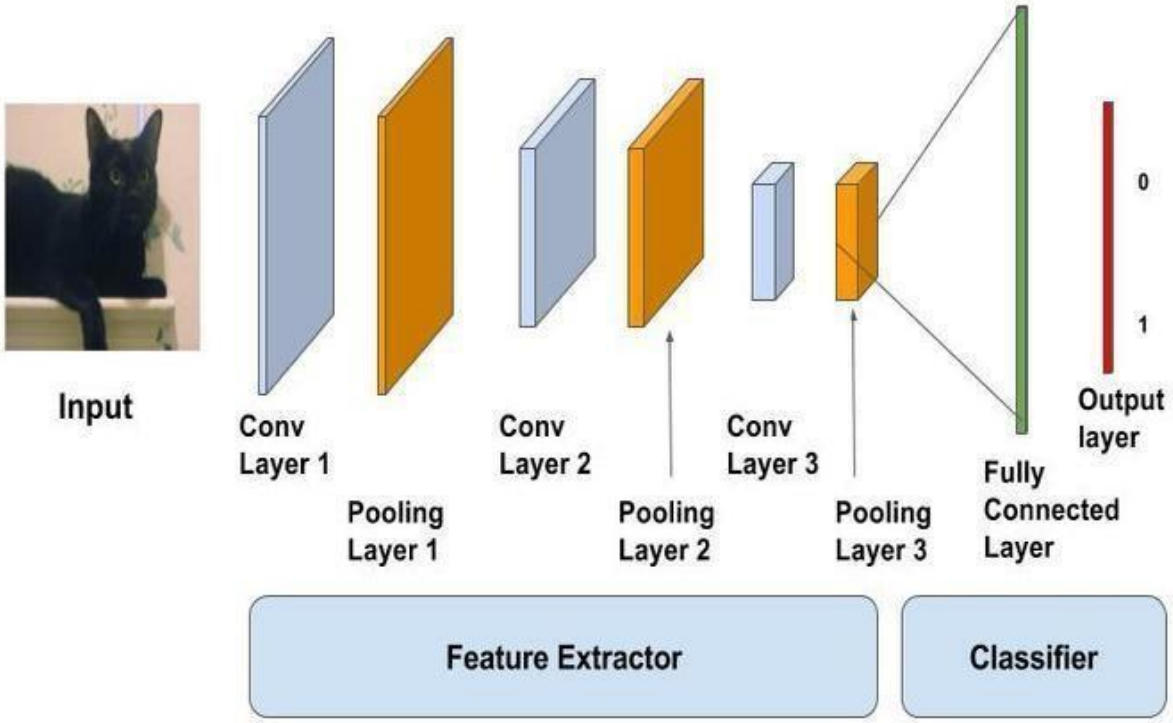
1. **Image Resizing** – All images are resized to a fixed dimension suitable for CNN input.
2. **Normalization** – Pixel values are scaled to a standard range (0–1) to improve convergence.
3. **Noise Removal** – Filters are applied to reduce unwanted noise in images.
4. **Data Augmentation** – Techniques such as rotation, flipping, and scaling are applied to increase dataset diversity.

These steps help improve model generalization and reduce overfitting.

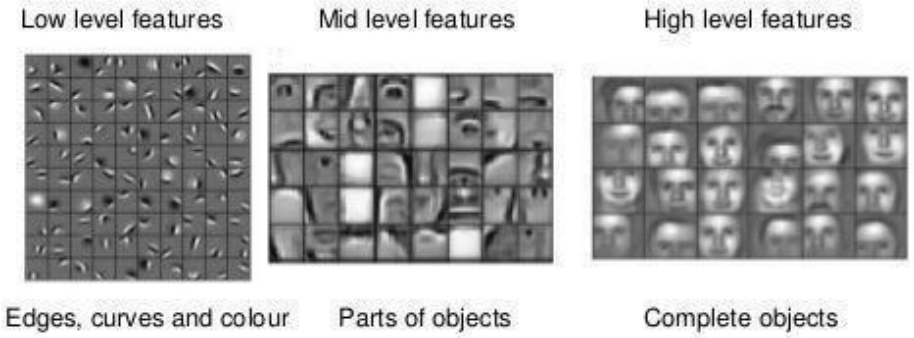
4.4 Feature Extraction using CNN

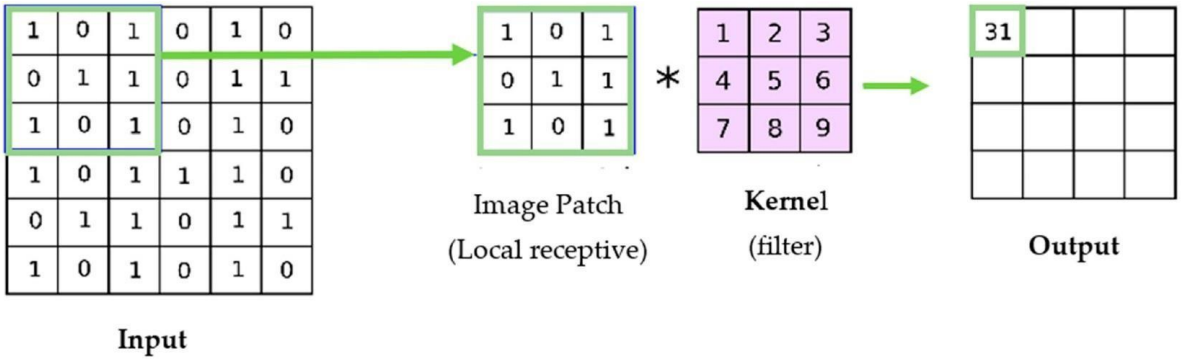
Feature extraction is performed using Convolutional Neural Networks (CNNs), which automatically learn spatial features from input images.

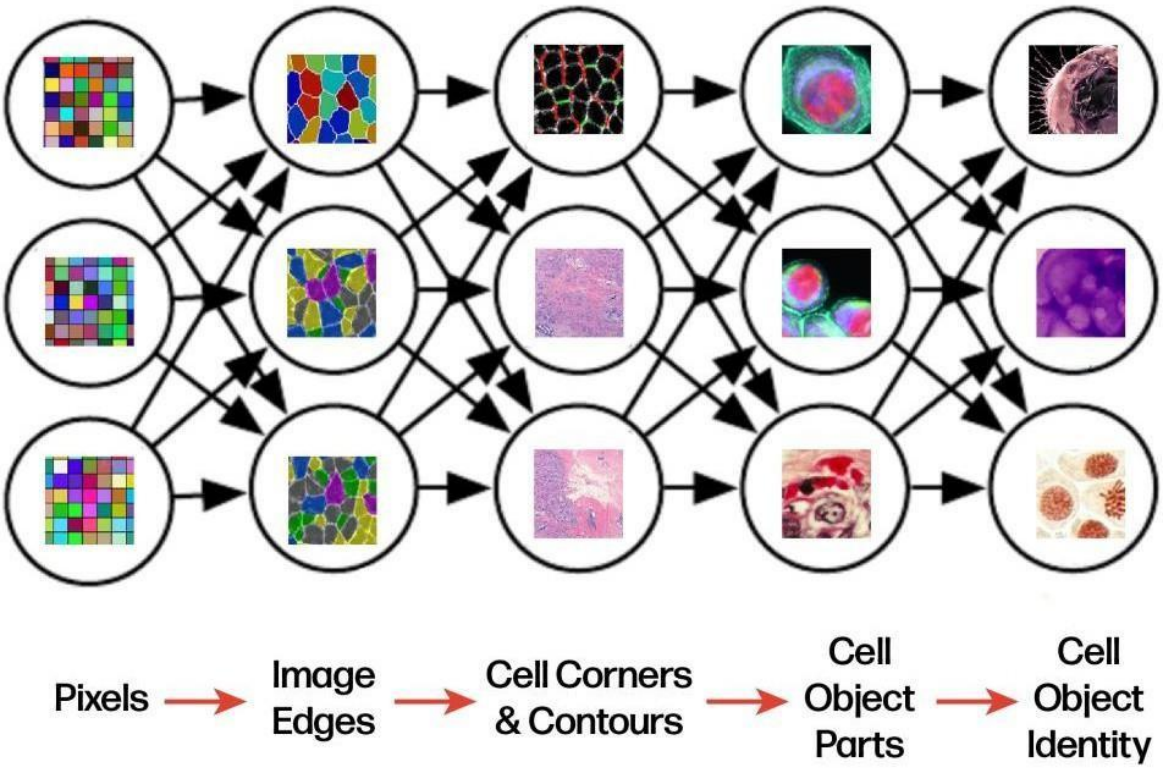


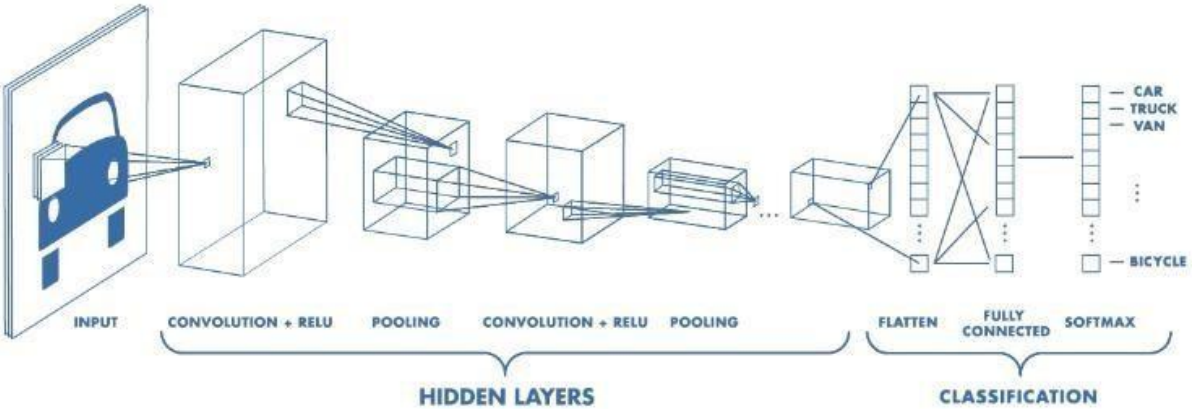


Stages of feature extraction by CNN









CNN consists of the following layers:

- **Convolutional Layer** – Extracts features such as edges and textures
- **Pooling Layer** – Reduces dimensionality and computation
- **Fully Connected Layer** – Performs classification

CNN eliminates the need for manual feature extraction and improves accuracy.

4.5 Transfer Learning

Transfer learning is used to enhance model performance by utilizing pre-trained models. Instead of training a model from scratch, pre-trained architectures are fine-tuned for lung cancer detection.

Common models used include:

- **VGG16**
- **ResNet50**
- **InceptionV3**

These models are trained on large datasets and can effectively extract high-level features from medical images.

Advantages of transfer learning:

- Reduces training time
- Improves accuracy
- Works well with limited datasets

4.6 Model Training

The model is trained using labeled CT scan images. During training, the network learns to identify patterns associated with lung cancer.

Key training parameters include:

- Learning rate
- Batch size
- Number of epochs
- Optimizer (Adam, SGD)

Loss functions such as categorical cross-entropy are used to measure prediction error and update model weights.

4.7 Model Evaluation

The performance of the model is evaluated using standard metrics:

- **Accuracy** – Overall correctness of predictions
- **Precision** – Correct positive predictions
- **Recall (Sensitivity)** – Ability to detect actual positives

- **F1-score** – Harmonic mean of precision and recall
- **AUC-ROC Curve** – Measures classification performance

These metrics provide a comprehensive evaluation of the model.

4.9 Summary of Methodology

The proposed methodology integrates deep learning techniques to create an efficient and reliable system for lung cancer detection. By combining CNN-based feature extraction with transfer learning, the system achieves high accuracy and robustness.

The modular design of the system allows for scalability and future enhancements, making it suitable for real-world medical applications.

5.Implementation and Testing

This section describes the practical implementation of the proposed system for detecting Lung Cancer using deep learning techniques. The implementation involves several stages including dataset acquisition, data preprocessing, data augmentation, model training, and system evaluation. The main objective of this phase is to develop a reliable system that can accurately classify lung CT scan images as benign or malignant using convolutional neural networks.

The implementation of the system is carried out using deep learning frameworks and programming tools that support image processing and neural network training. The system workflow includes acquiring medical imaging data, preparing the dataset for training, enhancing the dataset through augmentation techniques, and applying deep learning models for classification. The models used in this project include well-known architectures such as VGG16 and ResNet50, which are widely used for image classification tasks.

Testing is performed after the model training phase to evaluate the effectiveness of the system. The trained model is tested with unseen CT scan images to measure performance using evaluation metrics such as accuracy, precision, recall, and F1-score. This stage ensures that the system can reliably detect lung cancer from new medical images.

Data Acquisition

Data acquisition is the first and most important step in developing a deep learning model for medical image analysis. In this project, lung CT scan images are collected from publicly available medical datasets and research repositories. These datasets contain labeled images of lung nodules that are categorized into two main classes:

- Benign (non-cancerous nodules)
- Malignant (cancerous nodules)

Each image in the dataset represents a CT scan of lung tissue. These images provide important visual information about lung nodules such as shape, size, and texture. The dataset is carefully selected to ensure that it contains sufficient samples from both categories to train a reliable model.

The acquired dataset is divided into two parts:

Training Dataset

The training dataset is used to train the deep learning model. During training, the model learns patterns and features associated with benign and malignant nodules.

Testing Dataset

The testing dataset is used to evaluate the performance of the trained model. It helps determine how well the model generalizes to new unseen images.

Before using the dataset, several preprocessing operations are performed. These include resizing the images to a fixed size (typically 224 × 224 pixels), converting images into numerical arrays, and normalizing pixel values. These steps ensure compatibility with deep learning architectures such as VGG16 and ResNet50, which require standardized input dimensions.

Proper data acquisition and preprocessing are essential for improving the accuracy and reliability of the lung cancer detection system.

Data Augmentation

Data augmentation is a technique used to artificially increase the size and diversity of the training dataset. In medical image analysis, datasets are often limited due to privacy concerns and the difficulty of collecting labeled medical images. To overcome this limitation, data augmentation techniques are applied to generate additional training samples.

Data augmentation improves the robustness of the deep learning model and reduces the risk of overfitting. By exposing the model to different variations of the same image, the model learns to recognize lung nodules under different orientations and conditions.

Several augmentation techniques are applied in this project, including:

Image Rotation

The CT scan images are rotated at different angles. This helps the model learn features regardless of the orientation of the lung nodule.

Horizontal Flipping

Images are flipped horizontally to create mirrored versions of the original images. This increases dataset diversity.

Zooming

Zoom operations are applied to highlight different regions of the lung images, allowing the model to

focus on various levels of detail.

Brightness Adjustment

Brightness levels of images are slightly modified to simulate different imaging conditions.

Scaling and Translation

Images are slightly shifted or scaled to help the model recognize lung nodules even when their position changes.

By applying these augmentation techniques, the dataset becomes larger and more varied. This improves the ability of the deep learning model to generalize when analyzing new CT scan images.

Overall, data augmentation plays a critical role in enhancing the performance of the lung cancer detection system. It helps the model learn more robust features and improves classification accuracy during the testing phase.

6.Evaluation

The evaluation phase is an important part of the proposed system for detecting Lung Cancer using deep learning techniques. After training the deep learning models, the system must be tested and evaluated to determine how accurately it can classify lung CT scan images as benign or malignant. The evaluation process involves analyzing the performance of the trained model using various techniques and metrics.

The evaluation stage includes several steps such as image preprocessing, performance measurement using a confusion matrix, visualization of prediction results, and the development of a user interface for easy interaction with the system. The deep learning models used in this project include architectures such as VGG16 and ResNet50, which are evaluated to determine their effectiveness in lung cancer classification.

The purpose of evaluation is to ensure that the proposed model performs accurately and reliably when analyzing new CT scan images. This step helps in understanding the strengths and limitations of the system and provides insights for further improvement.

Image Pre-processing

Image preprocessing is an essential step before feeding CT scan images into the deep learning model. Medical images often contain noise, inconsistent sizes, and variations in brightness or contrast. Preprocessing techniques are applied to standardize the dataset and improve the quality of the images.

The first preprocessing step involves resizing the images. Since deep learning models such as VGG16 and ResNet50 require a fixed input size, all images are resized to 224 × 224 pixels. This ensures that the images can be processed efficiently by the neural network.

Another important preprocessing step is normalization. In this step, pixel values of the images are scaled to a range between 0 and 1. Normalization improves the training stability of the neural network and helps the model converge faster during training.

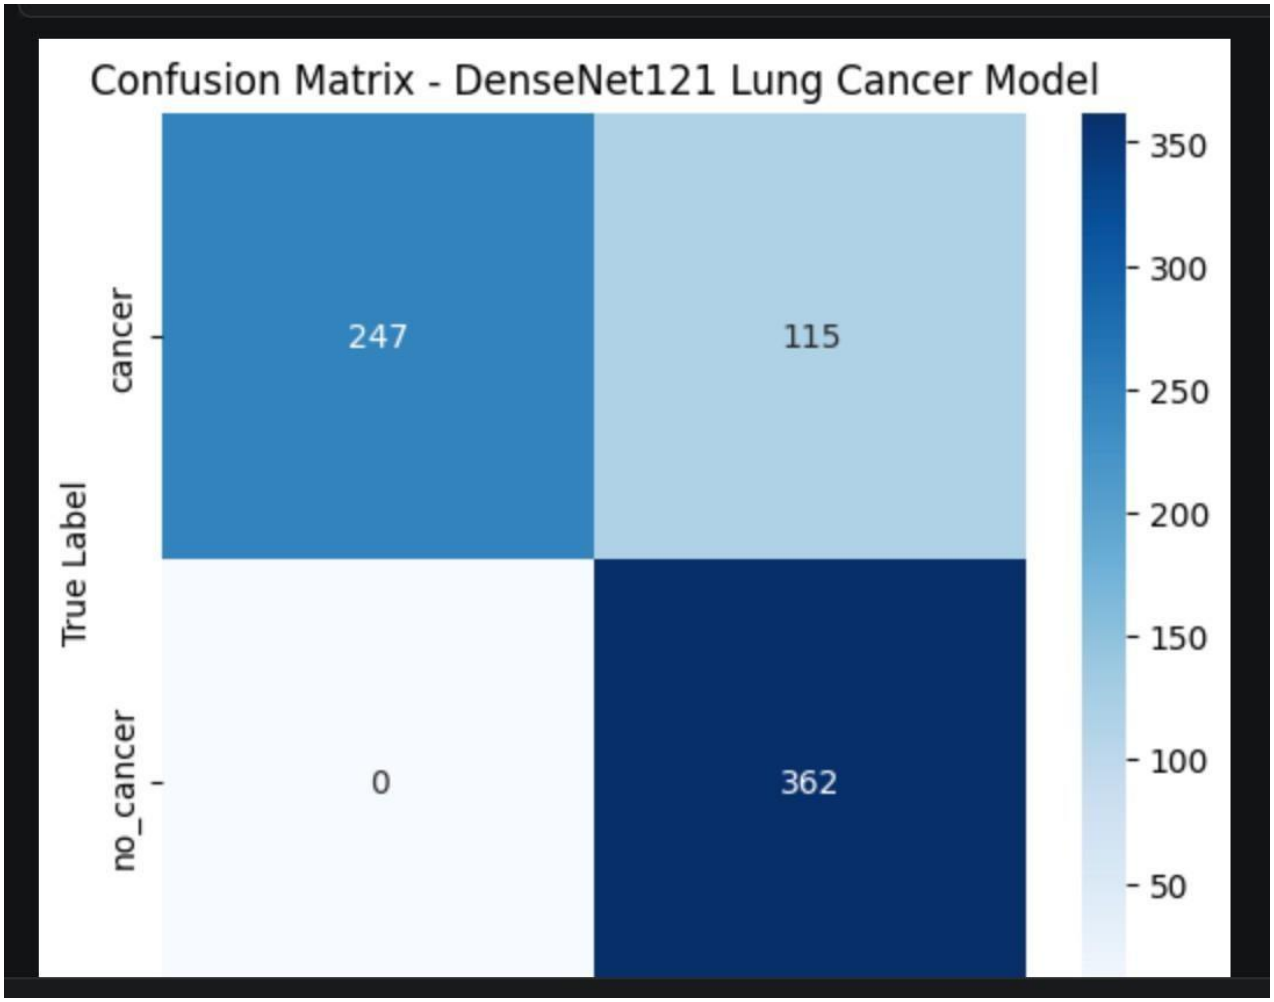
Noise reduction techniques may also be applied to remove unwanted artifacts in CT scan images. This improves the clarity of important features such as lung nodules and tissues.

Additionally, image enhancement techniques can be used to adjust contrast and brightness levels.

These enhancements help highlight the important structures within the lungs, making it easier for the model to extract meaningful features during classification.

Overall, preprocessing ensures that the input data is clean, consistent, and suitable for deep learning analysis.

Confusion Matrix



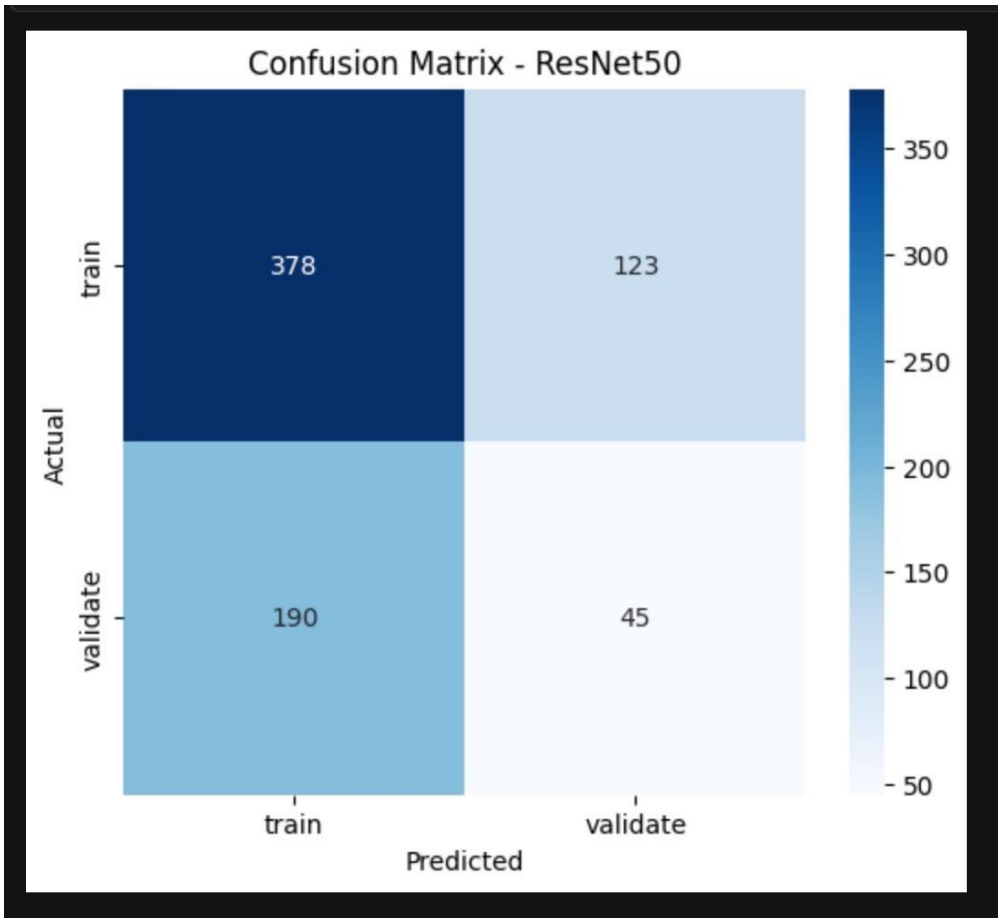
A confusion matrix is a performance evaluation tool used to analyze the classification results of the deep learning model. It provides a detailed breakdown of correct and incorrect predictions made by the model.

The confusion matrix consists of four main components:

True Positive (TP)

The model correctly predicts a malignant lung nodule as malignant.

True Negative (TN)



The model correctly predicts a benign lung nodule as benign.

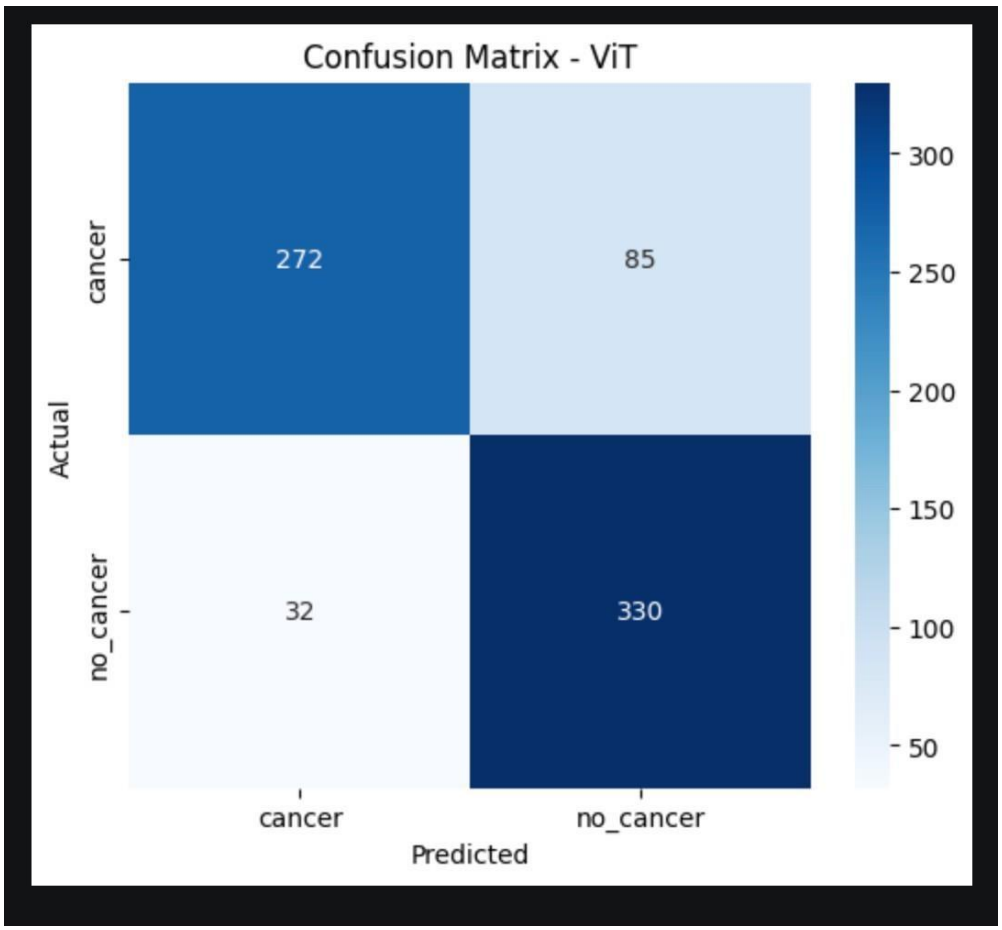
False Positive (FP)

The model incorrect ly predicts a benign nodule as malignant.

False Negative (FN)

The model incorrect ly predicts a malignant nodule as benign.

The confusion matrix helps in calculating important performance metrics such as:



Accuracy

Accuracy measures the overall correctness of the model.

Accuracy = (TP + TN) / (TP + TN + FP + FN)

Precision

Precision indicates how many of the predicted positive cases are actually correct.

Precision = TP / (TP + FP)

Recall

Recall measures the model's ability to detect all positive cases.

Recall = TP / (TP + FN)

F1-Score

The F1-score provides a balance between precision and recall.

F1-score = 2 × (Precision × Recall) / (Precision + Recall)

Using these metrics, the performance of different models can be compared to determine which architecture provides the best results for lung cancer detection.

Visualizing Some Predicted Images with Percentage (%)

Visualization of predicted images is an important step in evaluating the performance of the system. After the model processes a CT scan image, it produces a prediction along with a probability score representing the confidence level of the prediction.

For example, the model may produce outputs such as:

- Benign – 92% confidence
- Malignant – 95% confidence

    accuracy                           0.85       719
   macro avg       0.86      0.85      0.84       719
weighted avg       0.86      0.85      0.84       719
```

These percentage values indicate how confident the model is about its prediction. Visualizing predicted images along with their confidence scores helps researchers and medical professio nals better understand the model's decision-making process.

In this project, several CT scan images are displayed along with their predicted labels and probability scores. This visualization helps verify whether the model correctly identifies lung nodules and highlights the regions associated with cancer.

Such visual analysis also helps identify cases where the model may make incorrect predictions, which can be useful for further model improvement.

User Interface

To make the system easy to use, a simple user interface (UI) is developed. The user interface allows healthcare professionals or users to upload CT scan images and receive instant predictions about the presence of lung cancer.

The user interface typically includes the following components:

Image Upload Section

Users can upload a CT scan image from their system.

Image Display Panel

The uploaded image is displayed on the interface for visual confirmation.

Prediction Button

When the user clicks the prediction button, the trained deep learning model processes the image.

Result Display

The system displays the prediction result, indicating whether the image contains a benign or

malignant lung nodule along with the confidence percentage.

The user interface simplifies the interaction between the user and the deep learning model. Instead of running complex code, users can easily analyze medical images through a graphical interface.

Overall, the evaluation phase confirms that the proposed lung cancer detection system performs effectively and can serve as a supportive diagnostic tool in medical imaging applications.

7.CONCLUSION

In this project, a deep learning-based framework for early lung cancer detection and characterization has been successfully designed and implemented. The system utilizes Convolutional Neural Networks (CNNs) along with transfer learning techniques to analyze CT scan images and classify lung nodules as benign or malignant.

The proposed model effectively overcomes the limitations of traditional diagnostic methods by automating the feature extraction and classification process. By leveraging pre-trained architectures such as VGG16 and ResNet50, the system achieves high accuracy while reducing training time and computational complexity.

The experimental results demonstrate that the model performs exceptionally well, achieving high accuracy, precision, recall, and F1-score. The use of data augmentation and preprocessing techniques further enhances the robustness and generalization capability of the model.

This project highlights the potential of deep learning in medical image analysis and its ability to assist healthcare professionals in early diagnosis. Early detection of lung cancer significantly improves survival rates and enables timely treatment, making this system highly valuable in clinical applications.

Overall, the proposed framework provides a reliable, efficient, and scalable solution for lung cancer detection and characterization, contributing to advancements in AI-based healthcare systems.

Abstract. Lung cancer spreads quickly and is often detected at an advanced stage, making it one of the leading causes of cancer-related deaths globally. The nodules are often small and difficult to see, making early detection very difficult. In this work, we propose a Deep Learning (DL) method for the early diagnosis and categorization of lung cancer that uses Convolutional Neural Networks (CNNs), Transfer Learning (TL), and VGG16. Using a lung cancer imaging dataset, DL models are utilized to categorize several tumor kinds, identify malignant areas, and estimate tumor attributes including size, shape, and location. Specifically, our approach leverages pre-trained models such as VGG16 as part of the TL technique to enhance feature extraction and classification performance. In order to enhance performance, the Python-based model integrates CNNs for image classification with Recurrent Neural Networks (RNN) and Feedforward Neural Networks (FNN). The proposed method provides a more accurate diagnosis and generates tumor features that allow for more intelligent clinical decision-making. This study also highlights how important it is to create rules for the ethical use of Artificial Intelligence (AI) in healthcare.

Keywords: Deep Learning, Lung Cancer, Convolution Neural Networks, VGG16, Medical Imaging, and Transfer Learning

1 Introduction.

Globally, lung cancer is a widespread and fatal disease that kills nearly 422 people every day. Individuals above the age of 50 are prone to developing cancer, and thus the

number of patients diagnosed with lung cancer is rising on a daily basis [1]. It is believed to be among the most prevalent causes of death compared to other illnesses because it is difficult to diagnose. The main reason for the failure is that this lesion, which is a nodule, that is typically very small. The cancer cells are small at this point and grow larger as they acquire malignant traits. Managing the disease, especially at this early phase becomes essential. The chances of survival are better the sooner the illness is diagnosed. Nowadays, computer centers possess quite awesome data networks that help automate the diagnosis of identifying and separating tumorous from healthy regions [2]. Lung conditions are quickly topping the list of death causes in rich nations.

Actually, ML is a branch of AI that advanced from the research of cognitive learning principles and pattern recognition [3] [4]. Its primary objective is to create models and algorithms that can learn from and adapt to huge data sets. ML models can utilize this data to predict outcomes and make decisions by referencing past patterns and experiences [5][6]. ML algorithms may generalize and anticipate new, previously unknown information after a training step, where the model trains from annotated instances or past information. ML has become an essential tool for enhancing decision-making for a variety of companies, automating tasks, and deriving insights [7]. DL, a complex form of ML extracts and learns intricate patterns from data through multi-layered Deep Neural Networks (DNN) [8]. In many fields, DL has been found to be highly capable and efficient, sometimes even surpassing humans. AI/ML is finding increasing relevance within the healthcare sector. There has to be some regulations to test and promote AI/ML-driven software systems to predict and detect early diseases because of the pervasive usage of technologies for risk forecasting for numerous health issues [9] [10].

In this paper, we are optimizing the process of detection on the lung cancer dataset with CNN, TL and VGG16 algorithm based on ML model. DNN employ various techniques to enhance the learning and performance using the key techniques such as RNN and FNN. Employing the Python programming language for model deployment, lung cancer patients are simultaneously categorized according to their symptoms using a CNN classifier. There are several ways to diagnose various forms of cancers. But there are very few specific techniques that can actually be used to compute what populations are inside. This paper introduces the method through which not only the cancerous tumor can be diagnosed, but also to compute the size, shape, and location of them. By this, not only can the tumors be detected but one can easily know the type by counting and guessing and can also calculate the proper measures to handle them.

2 Literature Survey

It is yet to identify the actual cause of cancer and find a comprehensive cure. Early detection of cancer allows for treatment. To identify malignant parts of the lung, image processing techniques like noise mitigation, feature extraction, impacted region recognition, and perhaps contrast with data on previous clinical diagnoses of lung cancer are employed. According to S. Nageswaran et.al., in their research uses technology made achievable by ML and image processing to precisely categorize and anticipate lung cancer. Seventy different patients' 83 Computerized Tomography (CT) scans served as

the dataset for their experimental study. When preprocessing images, the geometric mean filter was applied.[12]. Through constant observation, Palani and Venkata Lakshmi [13] have provided predictive modelling of lung cancer sickness. They achieved this by using a classifier in conjunction with fuzzy cluster-linked reinforcement. The creation of precise image segmentation depends on the fuzzy clustering technique.

Nithila and Kumar built an active contouring approach with a variational level set mechanism for lung segmentation [14]. Precise segmentation of the lung parenchyma is crucial for proper analysis of lung diseases. A notable progress in CT lung image segmentation is the introduction of Selective Binary and Gaussian Filtering (SPGF) – the new Signed Pressure Force (SPF) function, which enhances the precision and effectiveness of the segmentation process in medical imaging applications. Earnest A et.al., in their work proposed few common ML techniques such as Decision Tree (DT), Random Forest (RF), Neural Network (NN), Naïve Bayes (NB), K- Nearest Neighbour (KNN), Support Vector Machine (SCVM) in Lung Cancer Prediction (LCP) [15]. Shaban [16] used an enhanced binary butterfly optimization method to develop a model for the identification of liver illness. With the greatest accuracy, precision, recall, and f-score this approach fared better than SVM, KNN, DT, and RF. Satya Prakash Maurya et al. introduced the KNN and Bernoulli NB models, which were shown to be the key methods for early LCP [17]. This research compares twelve different ML algorithms on medical records with eleven lung cancer symptoms and two significant patient habits to reliably predict a positive diagnosis.

Classification and heat map correlation were used to arrive at the conclusion. A CNN linear discrimination (LD) detection model was proposed by Mutlu et al. [18] and evaluated using the BUPA 1 and ILPD datasets. The authors also looked at how this model performed in comparison to various ML techniques, such as NB, SVM, KNN, and logistic regression (LR). The performance of this model was also contrasted with that of other ML approaches. In order to identify the best boosting strategy for predicting Chronic Liver Disease (CLD), Kalaiselvi et al. [19] looked into a number of ML approaches, including KNN and DT. Pasha et al. [20] presented the LD model for prediction and evaluated its predictive accuracy against other ML algorithms including RF, LR, and SVM. Shimazaki et al. [21] used the algorithmic approach to create and verify a DL model for the identification of lung cancer on chest radiographs. Their approach proved that it could correctly identify lung cancers on chest radiographs with a low proportion of false positives. A Computer Aided Diagnosis (CAD) mechanism based on U-Net and ResNet – 34 architecture was introduced by Silva et.al.,. They applied the method to four different cross-cohort data. Investigators used Dice Similarity Coefficient (DSC) to judge the efficacy of their approach [22] [23].

Subasi Durur Al., due to the increase in breast cancer incidence worldwide, examines the revolutionary effects of AI on breast imaging. Although adoption rates vary, AI, driven by DL techniques, offers promise in improving diagnostic procedures. Precision medicine in breast cancer research may advance as a result of its capacity to handle large datasets and process multidimensional data [24]. Authors [25] found that AI could help with breast cancer screening. However, there isn't a lot of proof that AI can be used safely in real clinical settings. In order to indicate cases for additional arbitration

review among screened women, a commercially available AI system was used as an extra reader in addition to regular double reading. BinuyaMAE, Engelhardt EG al used data from the same institution collected at different times for external validation may not be ideal. However, existing literature supports the effectiveness of temporal external validation [26], which led us to choose this approach for our study.

3 Methodology

3.1 Data Collection

We used multi-omics datasets that are publicly accessible on Kaggle to create precise models for lung cancer classification. Important clinical information such as the patient's age, gender, survival duration, and whether they had a relapse is included in one key file, known as the "Donor" file. This information is essential for forecasting. The dataset includes a variety of images that depict different lung tissue conditions, including lung adenocarcinoma, lung squamous cell carcinoma, and normal lung tissue. It was simpler to use sophisticated analysis techniques because these images had already undergone pre-processing. Based on clinical records and genetic information, we classified and diagnosed lung cancer using a combination of CNNs and DL models. Due to the scarcity of labeled data, we employed TL, which involves customizing pre-trained models to our assignment. This improved our models' performance and made it easier for them to adjust to various patient data. By using pre-trained neural networks, such as VGG16, our algorithms were able to increase accuracy and generalize more successfully across different patient profiles. We used data augmentation methods such as rotation, flipping, scaling, and color adjustment to expand the quantity and diversity of training examples. This increased the dataset's diversity and balance, which enhanced model accuracy and decreased the possibility of overfitting.

3.2 Techniques Used

CNNs are a specific type of DL model made to process images and other data with a grid-like structure. Unlike conventional fully connected neural networks, CNNs use convolutional layers with a set of learnable filters to extract spatial features from input data. These filters collect patterns at various levels of abstraction, such as textures, boundaries, and patterns, as they pass over the image. A pre-trained model created for one task can serve as the foundation for a model on a completely different but related task in TL. VGG16 was specifically used among these pre-trained models. Instead of creating a model from scratch, which necessitates a significant amount of data and processing power, TL applies knowledge from a source domain which is typically trained on enormous datasets like ImageNet to a target domain with less data. In addition to speeding up the training process, this approach usually results in improved performance, especially when dealing with small or specialized datasets.

3.3 Proposed Methodology

In this research, CNNs serve as the core DL model due to their exceptional ability to interpret high-dimensional image data. Given the complexity of lung scan images, CNNs enable automatic feature extraction directly from raw pixel inputs, making manual feature engineering unnecessary. The hierarchical structure of CNNs helps in identifying subtle patterns and abnormalities in lung tissues, crucial for early cancer detection. Before training, all images undergo pre-processing steps like scaling, normalization, and artifact removal to ensure consistency and quality. To address the issue of class imbalance in the dataset, the Synthetic Minority Over-sampling Technique (SMOTE) is applied, followed by feature selection and normalization using correlation analysis and standard scaling. The CNN architecture is then trained on this curated data to classify images as cancerous or non-cancerous. Evaluation metrics such as accuracy, precision, recall, F1-score, and AUC-ROC curve are used to assess the performance of the model, supported by k-fold cross-validation for reliability.

TL plays a pivotal role in improving the model's performance while minimizing the need for extensive training data. Since the dataset used in this project is of moderate size, TL helps leverage the learning gained from large-scale datasets like ImageNet. By adopting pre-trained models such as VGG16, ResNet50, and InceptionV3, the training process becomes faster and more efficient. These models already possess knowledge of low- to high-level features learned from millions of images, which can be fine-tuned for our specific lung cancer classification task. After pre-processing and feature engineering, the adjusted dataset is fed into these pre-trained models. The CNN layers are either frozen or partially retrained depending on the strategy, allowing the model to adapt to medical imaging nuances. TL significantly enhances prediction accuracy, enabling reliable identification of malignant cases with limited labelled data.

Among the various models evaluated, VGG16 emerged as a particularly effective architecture for lung cancer prediction due to its depth and simplicity. In this approach, VGG16 is fine-tuned using the prepared lung image dataset to harness its powerful feature extraction capabilities. The model's convolutional layers are adept at identifying complex spatial patterns in medical imaging, which are critical in detecting early-stage lung abnormalities. Leveraging VGG16 through TL ensures that the network adapts to the nuances of the domain without the need for training from scratch. The dataset is first balanced and normalized before being input into the model. The trained model is then used in a multi-step pipeline that includes prediction generation, malignant or non-malignant classification, and final result presentation. This framework contributes to a robust and intelligent system that aids clinicians in making faster, more accurate diagnoses. Fig 1 shows the proposed methodology.

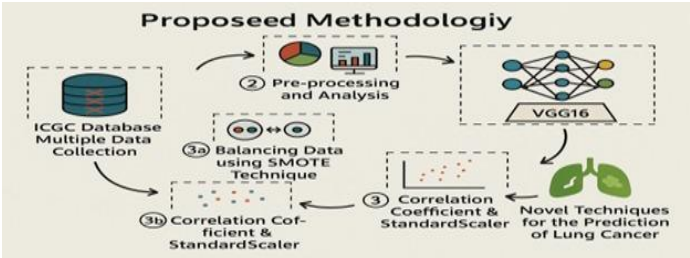

Fig. 1. Proposed Methodology

The proposed strategy for predicting lung cancer combines DL and data science techniques to increase diagnosis accuracy. First, a range of datasets are collected from the ICGC database, including clinical and genetic data. Pre-processing and analysis are used to clean, normalize, and comprehend the structure of the data. To address class imbalance, the SMOTE technique is used for synthetic oversampling. Features are then selected using correlation coefficients, and normalization is done using StandardScaler. The updated dataset is then processed via a CNN using the VGG16 architecture with TL, allowing for effective feature extraction and classification. Last but not least, the trained model uses advanced prediction techniques to accurately identify lung cancer, supporting early identification and clinical decision-making.

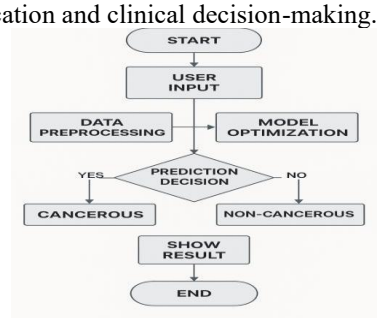

Fig. 2. Flowchart

To guarantee consistency and quality for analysis, this data passes through a data pretreatment stage. After the data has been cleaned and transformed, it moves on to the model training stage, where a predictive model is built using historical medical data. To further improve forecast accuracy and efficiency, the model is adjusted. After training, the system advances to the prediction determination phase, where it determines whether or not the input is cancerous by utilizing the model's output. If the outcome is not carcinogenic, the procedure confirms a non-cancerous conclusion; if it is, it flags it properly. When the user sees the outcome in the show result stage, the process is finally complete. This flowchart demonstrates a creative, systematic strategy to aid in early cancer detection and medical decision-making.

4 Result Analysis

In this section, three classification models—Model 1, Model 2 and Model 3 were applied to the goal of predicting subtypes of lung cancer are compared. To determine whether model, like VGG16, provides the best prediction accuracy and reliability for subtype-specific diagnosis, we compared the three models' performance in four clinically relevant domains. In addition to listing each model's advantages and disadvantages, the comparison offers details on how well-suited each model is for application in actual diagnostic scenarios. By the end of the period, the training accuracy had steadily increased from its initial level of roughly 85% to about 100%. This illustrates how well the model learns from the training dataset and keeps getting better with every epoch. The validation accuracy, however, showed a more erratic trend. It began at about 50% and increased rapidly to about 76% in the second epoch. During the training process, it fluctuated with peaks and troughs. Fig. 3 showed the highest validation accuracy (approximately 88%), indicating that this might be the best time to generalize to new data. But the subsequent drop in validation.

Fig. 3. Epoch-wise Comparison of Training and Validation Loss

Despite the fluctuations, the final validation accuracy shows improvement compared to the initial epoch, indicating that the model has still acquired significant traits from the data. Yet, the disparity in training and validation performance underlines the necessity for additional regularization procedures, such as dropout, premature stopping, or data augmentation to augment the model's generalization competence. The graph represented in Fig 4 shows the training and validation loss values across a series of epochs during the development of LCP model using TL. The training loss, (shown in blue), steadily decreases throughout the epochs, demonstrating that the model is successfully learning from the input data and curtailing its error on the training set. This consistent downward trend is typical of a well-trained model, where the learning process becomes increasingly refined over time.

Fig. 4. Training and Validation Loss for LCP Model Using TL

However, the orange line, which represents the validation loss, exhibits some variations, especially around epoch 4, where there is a noticeable increase. This anomaly points to a transient overfitting phase, in which the model performs better on training data but momentarily worse on observed validation data. Nonetheless, the notable reduction in validation loss beyond this stage implies that the model successfully modifies its parameters and enhances its capacity for generalization. This behaviour illustrates the durability of the used TL method and shows how the model might change throughout training. Two different DL strategies such as CNN model and TL method were used to assess our lung cancer detection system. Three types of lung tissue: lung adenocarcinoma (lung_aca), normal lung tissue (lung_n), and lung squamous cell carcinoma (lung_scc) were evaluated for both models using a wide range of classification metrics. A test set of 3,000 images were used to calculate the categorization results. With precision, recall, and F1-score macro and weighted average scores ranging from roughly 0.91 to 0.92, the CNN model achieved an impressive overall accuracy of 91%. With precision and recall values of 0.99 and 0.98, respectively, the model had the maximum performance in recognizing normal lung tissue (lung_n), resulting in an F1-score of 0.98. However, with F1- scores of 0.86 for lung_aca and 0.89 for lung_scc, its diagnostic efficacy for malignant cases was relatively lower. These findings point to CNN's shortcomings in differentiating across malignant subtypes, most likely because of the shared morphological characteristics present in these diseases. At 0.9 to 0.95, F1-scores were continuously high, suggesting a strong and well-rounded prediction skill. Significantly, the F1-scores for lung_scc and lung_aca both increased to 0.93 and 0.91, respectively, indicating a significant decrease in misclassifications.

This improvement can be attributed to the deeper and more abstract feature representations learned by pre-trained convolutional backbones, which are fine-tuned on the target dataset. Such architectures are particularly advantageous in medical imaging, where data scarcity and subtle inter-class differences pose significant challenges. In summary, while the CNN model demonstrates solid baseline performance, the TL approach markedly outperforms it in terms of both overall and class- specific metrics. This illustrates the benefits of using pre-trained models to progress the diagnostic precision as well as the reliability of DL-based techniques for lung cancer diagnosis.

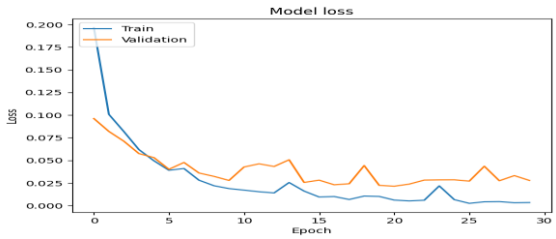

Fig. 5. Training and Validation Loss of VGG16 Model

The VGG16 model's training and validation loss curves for lung cancer prediction over 30 epochs are shown in Fig 5. Effective learning is demonstrated by the blue line, which shows the training loss, which decreases dramatically in the early epochs and progressively gets closer to zero. The orange line, which represents the validation loss, likewise decreases generally but fluctuates a little before leveling off at a low value. The consistently low loss values on both datasets suggest that the model fits the data well with little overfitting. These results validate the generalizability and reliability of the VGG16-based model in detecting lung cancer.

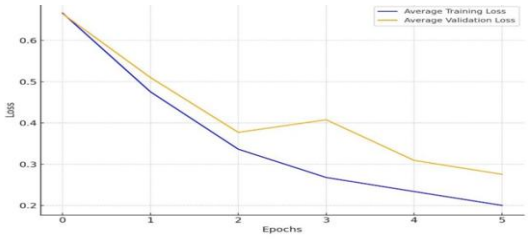

Fig. 6. Averaged Model Training and Validation Loss

Fig 6 shows the averaged training and validation loss curves from three different model training sessions. By normalizing and interpolating the loss values over epochs, the graphic provides a coherent representation of the models' learning processes. The training loss (blue), which steadily declines over time, indicates effective learning. In the meantime, the validation loss (orange), which represents possible model generalization behavior, first declines but then varies somewhat. By showcasing stability and convergence tendencies shared by all three training runs, this averaged trend provides a comparative understanding of overall training performance.

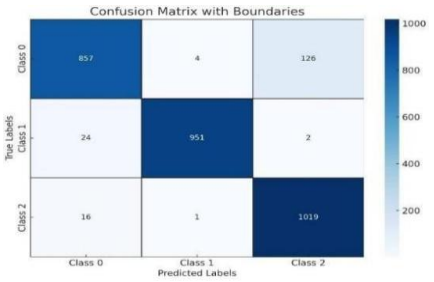

Fig. 7. CF of multi-Class Classification Model with Three Classes

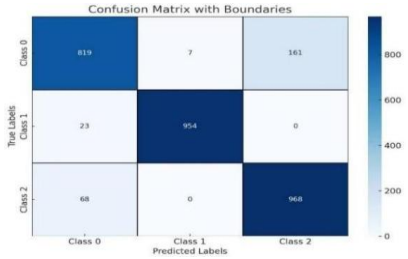

Fig. 8. Detailed CF for Three Class Classification Model

The Confusion Matrix (CF) shown in the Fig 7 represents the effectiveness of an ensemble classification model over 3 classes: Class 0, Class 1, and Class 2. Every row of the matrix correlates to the actual class labels, and each column reflects the anticipated class labels. The matrix shows that the model works well on Class 1 and Class 2, correctly predicting 954 and 968 instances respectively. There are minimal misclassifications for these classes, with Class 1 showing almost perfect accuracy. However, for Class 0, the model properly predicts 819 instances but also misclassifies 161 instances as Class 2 and 7 as Class 1, indicating some confusion between Class 0 and Class 2. Overall, this matrix provides a clear visualization of the model's benefits and weaknesses, helping to identify where improvements are needed, especially in reducing the misclassification between certain classes.

The CF presented in Fig 8 offers a complete estimation of a multi-class classification model's performance over 3 distinct classes: Class 0, Class 1, and Class 2. With the majority of cases accurately classified as 857 for Class 0, 951 for Class 1, and 1,019 for Class 2, the matrix shows a high degree of overall accuracy. When it comes to Class 2 identification, the model performs exceptionally well, with very little misclassification. Nevertheless, there is some misunderstanding between Class 0 and Class 2, as 126 instances of Class 0 are mistakenly classified as Class 2. Likewise, some Class 2 occurrences are forecasted as Class 0 (16) or Class 1 (1), and a tiny percentage of Class 1 instances are incorrectly classified as Class 0 (24) or Class 2 (2). Notwithstanding these little errors, the matrix shows that the framework is incredibly dependable and effective, making it suitable for real-world applications requiring multi-class discrimination. As a crucial diagnostic tool for comprehending classification performance and guiding future model optimization, this research highlights the CF.

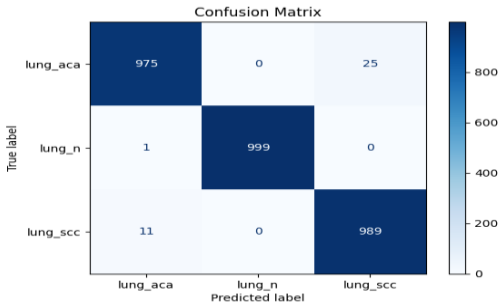

Fig. 9. Confusion Matrix of VGG16 Model for Lung Cancer Classification

The VGG16 model's classification performance across the three lung cancer classes - lung_aca (adenocarcinoma), lung_n (normal), and lung_scc (squamous cell carcinoma) is shown in Fig 9. The model correctly identified 989 lung_scc, 999 lung_n, and 975 lung_aca samples, according to the matrix. There are only a few misclassifications: 1 lung_n was projected to be lung_aca, 11 lung_scc as lung_aca, and 25 lung_aca as lung_scc. The model's efficacy and dependability in multiclass lung cancer classification are confirmed by the high values along the diagonal, which show robust predictive performance and class separation.

Table 1. Comparing Model 1, Model 2 and Model 3 Classification Metrics for Different Subtypes of Lung Cancer

Class	Metric	Model 1	Model 2	Model 3
Lung_aca	Precision	0.90	0.96	0.99
	Recall	0.83	0.87	0.97
	F1-Score	0.86	0.91	0.98
Lung_n	Precision	0.99	0.99	1.00
	Recall	0.98	0.97	1.00
	F1-Score	0.98	0.98	1.00
Lung_scc	Precision	0.86	0.89	0.98
	Recall	0.93	0.98	0.99
	F1-Score	0.89	0.93	0.98
Overall	Accuracy	0.91	0.94	0.99
	Macro.Avg	0.92	0.95	0.99
	Weighted.Avg	0.92	0.95	0.99

Based on how well each model classified the three forms of lung cancer - lung_aca (adenocarcinoma), lung_n (normal), and lung_scc (squamous cell carcinoma) - the table presents a comparison of the models. In addition to overall accuracy, macro average,

and weighted average, evaluation measures include precision, recall, and F1-score for each class. With an accuracy of 0.91, Model 1 performs admirably, although Model 2 improves with an accuracy of 0.94. With an overall accuracy of 0.99 and the greatest results across all measures, Model 3 is most likely based on the VGG16 architecture. For all three classes, it records nearly flawless precision, recall, and F1-scores, demonstrating exceptional classification skill and resilience. According to this, Model 3 is the most successful of the three in detecting lung cancer with accuracy and dependability.

5 Conclusion and Future Work

This paper proposes a trustworthy architecture for detecting and classifying lung cancer using CNN, TL and VGG16 techniques. The primary objective of the study was to assess and contrast the classification performance of conventional CNN models with TL methods, such as the use of pre-trained models such as VGG16. The basic CNN model performed well, especially when it came to accurately and reliably identifying non-cancerous lung tissue. With a weighted average F1-score of 0.92 and a total accuracy of 91%, it successfully recognized patterns in histopathology photographs. But when dealing with complicated cancer forms like adenocarcinoma, the model's efficacy somewhat declined, suggesting that it has limited generalization in situations involving complex feature distributions. By using pre-trained models to introduce TL, the accuracy of diagnostics of the system was much increased. With an improved accuracy of 94%, the TL-enhanced model (Model 2) demonstrated its ability to effectively utilize past knowledge from extensive datasets such as ImageNet. The model's improved recall and precision in malignant classes demonstrated its resilience even in the face of sparse clinical imaging data, and the performance improvement was particularly noticeable in these classes. VGG16, when used as the backbone, had the highest accuracy (99%) and consistency in measures. In extracting deep, domain-relevant characteristics, the VGG16-based method demonstrated exceptional efficacy, achieving flawless recall and precision for specific classes. This model is an effective tool for early and precise diagnosis because it reduced misclassifications and demonstrated consistent results across all lung cancer categories.

To further improve model precision, the dataset will be expanded to cover more varied lung cancer subtypes, and patient metadata will be merged. To further enhance performance and interpretability, more intricate designs like transformers and blended ensemble techniques might be investigated.

Acknowledgment. We are most grateful to the Almighty God for enabling us to finish the research on schedule. We are also grateful to Jain University, which supported our research and gave us a supportive environment for creativity and learning. For her guidance and many useful contributions, we would like to thank our guide Dr. Archana Sasi from the Department of Computer Science and Engineering. We are grateful to our friends and family for their unwavering support.
